May I again make a few suggestions for serious consideration by the B.M.A.?

- (1) Provide adequate capitation fee and *no* sliding scale.
- (2) Restrict doctors' lists to 3,000 or under.
- (3) Let doctors with lists in excess of this be advised, later directed if necessary, to take on *another* doctor (not assistant), but
- (4) In the name of all justice and fairness (not to mention common sense) let executive councils pay the new doctor for the number of patients he is brought in to take over.
- (5) If a sliding scale of capitation fee is to be used the new doctor, even with a list of 1,000, should benefit from the increased capitation fee for the first 1,000. I am sure no doctor with a sense of fairness would object to this.
- (6) Regarding the free choice of doctor one hears so much about, his is liable to cut both ways. A good "new doctor" with an interest in his work would soon have more patients than he could handle. But patients who wish to transfer to him should put his name on their cards, and executive councils should pay him for these patients who transfer. This would encourage all doctors to give of their best. Why make it all one-sided and study the old G.P.s only?

Give the younger men, married and single, and in particular the ex-Servicemen with wives and children who are here to get started and do a good job of work, encouragement and a fighting chance. Surely it is the object of the N.H.S. to provide a good service. Let it then provide for the men and women willing to give that service and make it a success.—I am, etc.,

ASSISTANT.

Trainee Specialists Association

SIR,—A Trainee Specialists Association in the North-West Metropolitan Region has been formed. The objects of the association are to further the professional interests and well-being of the trainee specialists. Will all hospitals which have not been notified to date accept the apologies of the Working Committee?

The next meeting will be held at Charing Cross Hospital on Monday, May 9, at 5 p.m. in the board-room, and it is hoped that all hospitals in the Region will send representatives.—I am, etc.,

A. B. BACKUS,
Chairman, Working Party.

25, Hospital Bridge Road,
Twickenham, Middlesex.

POINTS FROM LETTERS

Pay or Go Without

Dr. R. E. M. COKE HARVEY writes: Mr. X, who required merely a new frame for spectacles which suit him perfectly, called at an optician's shop. There he was informed that under the N.H.S. he could not have a new frame without making an appointment with the optician to test his eyes (unless he demanded to see a specialist); that such an appointment could not be made before April; that the specialist's prescription for the spectacles X does not need to change counted for nothing as against the optician's test. When X protested that the lenses were sound and all he needed was to have a fresh frame, the optician told him, "It is up to you to pay for them if you want them quickly." This, Sir, looks to me like the beginning of a racket which, unless nipped in the bud, will be able to trade on the urgency of the need of the myopic. I do not like the implied threat of "Pay or go without"; I do not see why an optician should be able to question a specialist's prescription, and indeed re-prescribe. . . .

Foreign Visitors

Dr. G. R. FABER (Maidstone, Kent) writes: It is reasonably obvious that public opinion is against free medical provision for foreign visitors, and I believe that if the profession would mutually decline to accept such persons as Health Service patients the general public would acclaim us, and the Government would alter their present attitude to this problem.

B.M.A. LIBRARY

The following books have been added to the Library:

- Adrian, E. D.: *Physical Background of Perception*. 1947.
Advances in Military Medicine. Two volumes. 1948.
 Appleton, A. B., Hamilton, W. J., and Tchaperoff, I. C. C.: *Surface and Radiological Anatomy*. Third edition by A. B. Appleton *et al.* 1948.
 Bailey's *Textbook of Histology*. Twelfth edition revised by P. E. Smith and W. M. Copenhaver. 1948.
 Bancroft, F. W., and Wade, P. A. (Editors): *Surgical Treatment of the Abdomen*. 1941.
 Barton, B.: *And Now to Live Again*. 1948.
 Berson, M. I.: *Atlas of Plastic Surgery*. 1948.
 Biggart, J. H.: *Pathology of the Nervous System*. Second edition. 1949.
 Blackie, W. K.: *Malaria: with special reference to the African forms*. 1947.
 Buchanan, A. R.: *Functional Neuro-anatomy*. 1948.
 Cameron, H. C.: *Joseph Lister: the friend of man*. 1948.
 Clarke, H. T., *et al.*: *A Symposium on the Use of Isotopes in Biology and Medicine*. 1948.
 Corlette, C. E.: *A Surgeon's Guide to Local Anaesthesia*. 1948.
 Corner, G. W. (Editor): *The Autobiography of Benjamin Rush*. 1948.
 Cowan, A.: *Refraction of the Eye*. Third edition. 1948.
 Craig, C. F.: *Laboratory Diagnosis of Protozoan Diseases*. Second edition. 1948.
 Crew, F. A. E.: *Measurements of the Public Health: essays on social medicine*. 1948.
 Cunningham's *Manual of Practical Anatomy*. Eleventh edition revised and edited by J. C. Brash. Volume 1. 1948.
 East, T.: *Cardiovascular Disease in General Practice*. Third edition. 1949.
 Egel, P. F.: *Technique of Treatment for the Cerebral Palsy Child*. 1948.
 Egerton, A. A., and Wolff, D.: *Histopathology of the Ear, Nose, and Throat*. 1947.
 Flack, I. H.: *Lawson Tait, 1845-1899*. 1949.
 Franklin, K. J.: *Cardiovascular Studies*. 1948.
 Giglioli, G.: *Malaria, Filariasis, and Yellow Fever in British Guiana*. 1948.
 Gilroy, A. B.: *Malaria Control by Coastal Swamp Drainage in West Africa*. 1948.
 Guttmacher, A. F.: *The Story of Human Birth*. 1949.
 Hale-White, W.: *Materia Medica, Pharmacy, Pharmacology, and Therapeutics*. Twenty-eighth edition revised by A. H. Douthwaite. 1949.
 Heaton, T. G.: *Artificial Pneumothorax in Pulmonary Tuberculosis*. Second edition. 1947.
 Herbut, P. A.: *Surgical Pathology*. 1948.
 Hess, W. R.: *Die funktionelle Organisation des vegetativen Nervensystems*. 1948.
 Hevesy, G.: *Radioactive Indicators*. 1948.
 Housden, L. G.: *Handbook of Parentcraft*. 1948.
 Huffman, E. K.: *Manual for Medical Records Librarians*. Second edition. 1948.
 Jagenfritz, H. C.: *Preoperative and Postoperative Care of Surgical Patient*. 1948.
 Isaacs, S.: *Childhood and After*. 1948.
 Israëls, M. C. G.: *An Atlas of Bone-marrow Pathology*. 1948.
 Jones, E.: *Papers on Psycho-analysis*. Fifth edition. 1948.
 Joslin, E. P.: *Diabetic Manual for the Doctor and Patient*. Eighth edition. 1948.
 Kayne, Pagel, and O'Shaughnessy's *Pulmonary Tuberculosis*. Second edition revised and partly rewritten by Walter Pagel *et al.* 1948.
 Kendall, J. I.: *Microscopic Anatomy of Vertebrates*. Third edition. 1947.
 Kraines, S. H.: *Therapy of the Neuroses and Psychoses*. Third edition. 1948.
 Lawrence, R. D.: *The Diabetic A B C: a practical book for patients and nurses*. Tenth edition. 1948.
 Libman, E., and Friedberg, C. K.: *Subacute Bacterial Endocarditis*. Second edition. 1948.
 Lillie, R. D.: *Histopathologic Technic*. 1948.
 Luisada, A. A.: *Heart: a physiologic and clinical study of cardiovascular diseases*. 1948.
 Marindale, H.: *Some Victorian Portraits and Others*. 1948.
 Means, J. H.: *The Thyroid and its Diseases*. Second edition. 1948.
 McKie, E. C., and Mackenzie, I.: *Handbook of Surgery*. Second edition. 1949.
 Moss, J.: *Health and Welfare Services Handbook*. 1948.
 Padgett, E. C., and Stephenson, K. L.: *Plastic and Reconstructive Surgery*. 1948.
Recent Progress in Hormone Research. Volume 3. 1948.
 Soffer, L. J.: *Diseases of the Adrenals*. Second edition. 1948.
 Solé, A.: *Technik der Kinderärztlichen Differentialdiagnostik*. 1948.
 Southgate, B. A.: *Treatment and Disposal of Industrial Waste Waters*. 1948.
 Swire, M. E.: *Handbook for the Assistant Nurse*. 1949.
 Whillis, J.: *Elementary Anatomy and Physiology*. Third edition. 1949.
 Wolberg, L. R.: *Medical Hypnosis*. Two volumes. 1948.
 Wolf, G. D.: *Ear, Nose, and Throat: symptoms, diagnosis, treatment*. 1947.
 Zeta: *The Diagnosis of the Acute Abdomen in Rhyme*. Second edition. 1949.

Association Notices

COUNCIL OF THE B.M.A.

Election of 22 Members by Grouped Branches in the British Isles, of 2 Public Health Service Members, and of 1 Woman Member

The following have been elected for the session 1949-50:

North of England Branch:	Weldon P. T. Watts, Newcastle-upon-Tyne.
East Yorkshire and Yorkshire Branches:	Ian G. Innes, Hull.
Isle of Man, and Lancashire and Cheshire Branches:	Percy Malpas, Liverpool
Derbyshire, Leicestershire and Rutland, Lincolnshire, and Nottinghamshire Branches:	D. R. Owen, Chester.
North Wales, and Shropshire and Mid-Wales Branches:	J. Cottrell, Grimsby.
South Wales and Monmouthshire Branch:	D. B. Evans, Coedpoeth.
Bath, Bristol, and Somerset, Gloucestershire, and Worcester-shire and Herefordshire Branches:	J. W. Tudor Thomas, Cardiff.
Southern and Surrey Branches:	H M Golding, Bristol
Kent and Sussex Branches:	N. E. Waterfield, Little Book-ham.
Aberdeen, Dundee, Northern Counties of Scotland, and Perth Branches:	R. P. Liston, Tunbridge Wells.
Edinburgh and Fife Branches:	Mary Esslemont, Aberdeen.
Glasgow and West of Scotland Branch (Glasgow Division):	J. G. M. Hamilton, Edinburgh
Border Counties, Glasgow and West of Scotland (Five County Divisions), and Stirling Branches:	W. M. Knox, Glasgow.
	W. Jope, High Blantyre.

The following candidates have been nominated:
Bedfordshire, Cambridge and Huntingdon, Essex, Hertfordshire, Norfolk, Northamptonshire, and Suffolk Branches:
Metropolitan Counties Branch:

A. Staveley Gough, Watford
J. C. Pearce, Diss.
R. Nelson Ford, S.W.10
J. A. Gorsky, S.W.1.
E. Gray, W.C.1.
R. Hale-White, N.W.1
Lord Horder, W.1.
J. F. Murphy, S.W.8
Eric Steeler, W.1.
G. de Swiet, W.10.

Dorset and West Hants, South Western, and Wiltshire Branches:

J. A. Pridham, Weymouth
S. Noy Scott, Plympton.

Voting papers will be issued to the members of these Groups on May 14, 1949.

No nominations have been received for Group F (Berks, Bucks, and Oxford, Birmingham, and Staffordshire); Group R (Northern Ireland).

PUBLIC HEALTH SERVICE

The following have been elected: C. Metcalfe Brown (Manchester); R. H. H. Jolly (Wolverhampton).

WOMAN MEMBER

Janet Aitken (London), being the only candidate nominated for election by women members, is elected as a member of Council, 1949-50.

CHARLES HILL,
Secretary.

Diary of Central Meetings

MAY

9 Mon	Joint Committee of B.M.A. and National Veterinary Medical Association, 2 p.m.
10 Tues	Conference of Honorary Secretaries of Divisions and Branches, 11.30 a.m.
11 Wed.	Council, 10 a.m.
24 Tues.	Scholarships and Grants Subcommittee, 11 a.m.
24 Tues.	British Pharmacopoeia Subcommittee, 2 p.m.
27 Fri.	Committee on the Postgraduate Education of General Practitioners, 2 p.m.
31 Tues	International Relations Committee, 2 p.m.

Branch and Division Meetings to be Held

BOURNEMOUTH DIVISION.—At Boscombe Hospital, Thursday, May 12, 8.15 p.m., annual Division meeting. Agenda: (1) Report of Representatives to Special Representative Meeting of March 29 and 30. (2) Instructions of Representatives to Annual Representative Meeting.

CAMBERWELL DIVISION.—At Dulwich Hospital, Friday, May 13, 8.30 p.m., annual general meeting. Dr. Charles Grosse: "Black Medicine."

EAST SOMERSET DIVISION.—At Small Hall, Wells, Sunday, May 8, 3 p.m., general meeting.

HASTINGS DIVISION.—At Royal East Sussex Hospital, Wednesday, May 11, 8.30 p.m., annual meeting.

HENDON DIVISION.—At Hendon Hall Hotel, Friday, May 13, 8.30 p.m., annual general meeting.

LEPDS DIVISION.—At Medical School, Wednesday, May 11 8 p.m., annual general meeting.

METROPOLITAN COUNTIES BRANCH.—At B.M.A. House, Tavistock Square, London, W.C., Thursday, May 26, 8 p.m. for 8.30 p.m. Charities Ball. Tickets, including a buffet supper, 2 guineas each, obtainable on application to the Secretary, the Charities Ball Committee, Metropolitan Counties Branch, B.M.A. House.

NORTHERN IRELAND BRANCH.—At New Nurses' Home, Royal Victoria Hospital, Grosvenor Road, Belfast, Wednesday, May 11, 10.30 a.m., annual meeting. 1.30 p.m., at Grand Central Hotel, Royal Avenue, Belfast, luncheon.

TUNBRIDGE WELLS DIVISION.—At Kent and Sussex Hospital, Wednesday, May 11, 8.15 p.m. Dr. P. M. F. Bishop: "Hormone Therapy."

H.M. Forces Appointments

ROYAL NAVY

ROYAL NAVAL VOLUNTEER RESERVE

Surgeon Commander H. P. Widdup, V.R.D., has been placed on the Retired List.

Surgeon Lieutenant-Commander D. M. Sheppard, D.S.C., has terminated his commission on transfer to the R.C.N.(R.).

Surgeon Lieutenant-Commander N. M. Hancox has been removed from the Active List.

Temporary Surgeon Lieutenant-Commander D. Ross has terminated his temporary commission.

Surgeon Lieutenants W. S. Johnston, J. C. Jones, and E. O. Davies D.S.C., to be Surgeon Lieutenant-Commanders

ROYAL AIR FORCE

E. W. R. Fairley to be Squadron Leader.

DENTAL BRANCH

D. C. P. Battersea to be Squadron Leader.

ROYAL AUXILIARY AIR FORCE

Wing Commander J. P. Huins, O.B.E., A.F.C., has relinquished his commission on appointment to the reconstituted R.A.F.V.R., retaining his rank.

ROYAL AIR FORCE VOLUNTEER RESERVE

Squadron Leader (Honorary) H. L. Walker has relinquished his commission on cessation of duty.

Squadron Leaders G. B. Grayling, O.B.E., M. L. Maley, and G. P. Arden have relinquished their commissions on appointment to the reconstituted R.A.F.V.R., retaining the rank of Wing Commander.

Squadron Leaders R. G. H. Cunningham and K. A. Boughton-Thomas have relinquished their commissions on appointment to the reconstituted R.A.A.F., retaining their rank.

Flight Lieutenant T. J. Evans has relinquished his commission on account of medical unfitness for Air Force service, retaining the rank of Squadron Leader.

Flight Lieutenants G. A. Mandow, F. W. Ford, and S. C. Frazer have relinquished their commissions on appointment to the reconstituted R.A.F.V.R., retaining the rank of Squadron Leader.

Flight Lieutenants J. D. Nelson and R. J. Gampell have resigned their commissions, retaining the rank of Squadron Leader.

Flight Lieutenant J. B. Good to be Squadron Leader.

COLONIAL MEDICAL SERVICE

The following appointments have been made: A. C. de C. Kerr, M.R.C.S., Medical Officer, ... P. Fok ... Robertson ... M.B. ... F.R.C.S., Assistant Medical Officer, ... L.R.C.S., Assistant Medical Officer, Grade ... M.B. ... Medical Officer, North Borneo; H. ... M.B. ... Medical Officer, Grade "A" Surgeon, Trinidad; P. B. Adamson, M.B., Pathologist, Nigeria; T. F. Anderson, M.D., D.T.M.&H., Deputy Director of Medical Services, Kenya; D. A. Baird, M.B., Senior Medical Officer, British Somaliland; A. J. Board, M.B., D.T.M., and T. Evans, M.R.C.S., D.P.H., Senior Medical Officers, Northern Rhodesia; K. Edmundson, M.B., Assistant Director of Medical Services, Tanganyika; H. S. Rassim, M.R.C.S., D.M.R.E., Radiologist, Hong Kong; J. I. Rerrie, M.R.C.S., D.P.H., Tuberculosis Officer, Jamaica.

EXTRATHORACIC PAIN IN CARDIOVASCULAR DISEASE*

BY

J. L. LOVIBOND. M.D., F.R.C.P.

Assistant Physician, Westminster Hospital; Assistant Cardiologist, London Chest Hospital

The pain which a crippled heart can inflict is one of the more frightening experiences of clinical medicine. To most of us its essential distribution and typical radiations have an accepted and well-recognized pattern. But occasionally cardiac pain is encountered whose qualities are different, or a pain from other causes in a disordered cardiovascular system occurs, for instance, in the head, in the limbs, or in the abdomen, and presents a less familiar problem of diagnosis.

The purpose of this paper is to present some conditions where extrathoracic pain is the dominant symptom of structural or functional cardiovascular disease and to explore its clinical significance. In reviewing a large subject the exclusion of chest pain will serve to emphasize other clearly defined syndromes of pain, some of which are perhaps not so widely recognized.

Pain is a prevalent symptom which is notoriously difficult to assess, being entirely subjective and dependent on the acuity of the individual's sensory perception and also on his ability to describe it in words. An attack of coronary thrombosis in a labourer may cause less constitutional disturbance than a chilblain in a typist. To judge the relative gravity of a pain it is therefore desirable, whenever possible, to witness its occurrence or at least, by interrogation, to record accurately the patient's personal statements; the description may be graphic and, as we shall see, sometimes distinctive. On the other hand, a painful episode becomes exaggerated in the telling of it, and this is proportional to the number of times the subject has been interrogated; due allowance must therefore be given to possible distortion of symptoms.

Headache

Headache more often than not is a symptom which recurs without signs. We can, however, distinguish several varieties which are peculiar to specific circulatory disorders, though it is not easy to find a single common cause. However, largely as the result of Pickering's (1933) studies on histamine headache, we recognize that pain perception arises in the tissues of the dura round the meningeal arteries, where the sensitive trigeminal nerve-endings are affected by stretching or traction. Pressure changes within the minute vessels of the brain are probably of importance in the pathogenesis of hypertensive headache.

The interpretation of headache calls for a very careful interrogation and clinical understanding of the patient: we must not forget that he or she may have two kinds of headache—the one perhaps of little consequence, while the other may be the symptom of a fatal illness.

Temporal arteritis is a malady of older age, and appears to be commoner in countrymen and countrywomen. Its special feature is a constant, dull, and throbbing pain in one or both temples, at times sharp, stabbing, and severe, aggravated by cold winds and by movements of the head. The headache tends to wax and wane, often enough preventing sleep, and persists for several months before gradually dying away. But it is also accompanied by a vague sense of malaise, weakness and fatigue, bodily aches, loss of weight, and low fever. Indeed, the patients seem ill out of all proportion to their physical signs, and may at the height of the disease become very ill indeed. The blood pressure is normal and there is no significant arteriosclerosis, but blindness may follow, due presumably to retinal ischaemia from involvement of the vessels behind the globe (Harrison, 1948). The temporal arteries are conspicuously thickened, nodular, and very tender. The overlying skin may be reddened and oedematous. Pulsation in them is diminished or absent. Histologically we find an inflammatory reaction in the adventitial coat, invading the media, with focal necrosis and granulation tissue in which giant cells are numerous. It seems probable that the arterial tree throughout the body is similarly affected, and there is a good deal of evidence to indicate that we are here considering a generalized disease, somewhat resembling polyarteritis nodosa, though with a better prognosis possibly because the kidneys are spared. Excision of a piece of the temporal artery for biopsy is followed by relief of the pain: procaine injections along the artery or of the stellate ganglion are said to have the same therapeutic effect (Roberts and Ashey, 1948).

The headache of *subarachnoid haemorrhage* is characteristic. I recall a patient who collapsed while pumping her bicycle. On regaining consciousness she recollected stooping over the punctured tyre, but insisted that someone had hit her across the back of the head with a steel bar, so sudden and arresting had been the onset of her pain. The rupture of the internal carotid aneurysm usually occurs on physical straining. Sudden agonizing headache is followed by clouding of consciousness, with evidence of meningism, a raised intracranial pressure, and blood in the cerebrospinal fluid. Sometimes localizing signs may appear, such as pulsating exophthalmos with knife-like retro-orbital pain or a third-nerve lesion with contralateral hemiplegia.

Aortic incompetence is occasionally attended by a troublesome pulsating headache.

A hairdresser, aged 45, had contracted a chancre at the age of 17 and was pronounced cured after three months' treatment. When using a hair-massage vibrator on a customer he was suddenly overcome by a noisy beating in his chest. At the age of 42 his blood Wassermann reaction had been found

*From a postgraduate lecture delivered on Jan. 28.

positive on routine testing as a blood donor, and antisyphilitic treatment was begun. In this attack he had no pain or breathlessness, but when examined a loud "twanging" diastolic murmur could be heard all over the chest, front and back, with a diastolic thrill present at the aortic area. Blood pressure was 220/40 and the pulse regular. Radioscopy showed slight general enlargement with increased pulsation, but a normal aorta. The blood W.R. was then negative. Six months later he developed a continuous occipital headache with violent throbbing in his temples. The collapsing nature of the pulse in his temporal, carotid, and subclavian arteries was so pronounced that it could best be described as "detonating." This prostrating headache was relieved by sleeping with the head propped up by pillows.

Here the symptoms were evidently related to the unusually high pulse pressure resulting from probable partial rupture of an aortic valve cusp.

Headache develops in prolonged *anoxia* and in *polycythaemia*, but in the cyanotic plethora of *superior caval obstruction* it is perhaps uncommon. Intense headache may be a symptom of *dissection of the aorta* involving the carotid artery.

Many patients with *hypertension* wake every morning with an occipital or frontal headache, which varies in degree from a dull ache to a savage pounding and then gradually wears off as the morning progresses, only to recur day after day for many weeks at a time. It seldom awakens the patient, unlike the pain of increased intracranial pressure, and is not affected by straining but only by posture. Possibly this particular headache is more frequent in the unstable case of early or mounting blood pressure, being a less common finding in long-established benign hypertension. On the other hand, it may disappear without any fall in pressure: moreover, some patients with high-grade hypertension (Group IV), papilloedema, and a raised C.S.F. pressure have no headache.

A number of remedies have been tried for this distressing symptom, but in my experience bed-rest with the head propped high on pillows, barbiturate sedation, and aspirin are as useful as any of the more active lines of treatment and have at least the advantage of simplicity. Venesection often relieves the patient for a few days, but lumbar puncture, intravenous sucrose, dehydration, thiocyanate therapy, and even thoraco-lumbar sympathectomy may all prove disappointing.

Fishberg (1948) points out that the relief of headaches, which lumbar sympathectomy undoubtedly does achieve, may be due to a resultant redistribution of cardiac output, with a reduction of the fraction going to the head and arms. As evidence for this post-operative redistribution of blood flow he cites the clinical finding of cooler hands and warmer feet and the phenomenon of postural hypotension. That the vascular territory is not in fact denervated is supported by the persistence after operation of retinal arterial narrowing in the absence of headache. One of the clinical circumstances where diminished blood flow to the head is usually attended by relief of hypertensive headache is with the appearance of congestive failure, when, though the systolic blood pressure falls, the diastolic remains high.

Angina

The conventional reference of cardiac pain to the throat, arms, or lower jaw is familiar. But problems of diagnosis arise when a referred pain occurs alone or with insignificant pain in the chest. I have known a patient consult his dentist because of severe aching pain in the teeth when walking in the cold air. This could be relieved by closing his mouth and resting for a few seconds, but was in fact a true anginal pain. Cardiac pain may arise predominantly in the arms.

A retired Army colonel of 65, three months after a coronary thrombosis from which he had made a good functional recovery, was having to get up several times a night with severe pain in both wrists, eased more by papaverine than by trinitrin. Aching pain in the left forearm and left-sided toothache had been a prominent accompaniment of the heavy sternal pain which woke him at 3 a.m. in his original attack. Serial cardiograms in this case were typical of anterior infarction of the left ventricle.

A departmental manager, aged 63, complained of bac neuralgic pains on exertion, eased at once by rest, which always started in his left arm below the elbow and radiated up the arm to the jaw, the suprasternal notch, and right chest. The pain was also brought on in bed by cold linen sheets. His cardiogram showed changes of posterior infarction, returning later to normal. This pain syndrome is an instance of so-called "reversed angina."

That the pain of angina may be felt in a phantom limb suggests that the pain reference is not a simple segmental sensory reflex but possibly depends on cortical connexions (Harman, 1948). A patient whose left arm was amputated 4 in. (10 cm.) below the elbow-joint developed angina pectoris and began to be troubled by pain on effort in the phantom hand of such severity that he was obliged to obtain a new artificial limb, thinking that the old bucket was chafing his stump.

In considering differential diagnosis it is wise to remember that in the older age groups where coronary disease is more prevalent many patients are also subject to spinal-root pains, fibrositis, and lumbago of varying degrees, due to spondylarthritis and other degenerative skeletal processes. Effort pain may then arise in the back and, resembling cardiac pain in its distribution, be referred to the front of the chest or abdomen, and sometimes to the arms. However, these pains typically come on, not on ordinary physical exertion, but with specific movements such as bending, turning, lifting weights, or straining. After prolonged sitting—e.g., in the cinema or at the wheel of their car—these individuals develop a restless discomfort, eased by standing up or stretching their back, not unlike the relief obtained in sufferers from hiatus hernia. Such symptoms can be reproduced by pressure over the dorsal vertebrae, by hypertonic saline injection of the interspinous ligament, or by forced flexion of the head, and alleviated by rehabilitation and orthopaedic correction of faulty posture (Davis, 1948).

Upper abdominal pain on exertion, eased by rest, but due to the hepatic congestion of early right heart failure, must also be distinguished symptomatically from angina pectoris. Patients may describe their distress as more of a feeling of epigastric fullness or discomfort on exertion than a pain; or they may state that the abdomen is "tender to the bedclothes." Occasionally an acute surgical abdominal incident, such as a perforated gastric ulcer, closely simulates coronary thrombosis, particularly during the initial stages. After the first twenty-four hours, however, the distinction more often than not becomes apparent.

Pain in the Hands

We have seen that both angina and fibrositis can cause pain in the arms, but now and then a cramp-like pain arises in the arms of manual workers with repeated muscular use of those limbs which is due to *obliterative arterial disease*—an ischaemic manifestation identical with claudication in the legs.

An upholsterer, aged 53, whose work involved the pulling and stretching of heavy materials to cover sofas, complained for four years of an aching, stiff pain in the forearms and backs of the hands, mainly right-sided. He habitually experienced this pain at his work, particularly in the cold and

towards the end of a heavy week, yet it always subsided at once on resting. He had no other symptoms, and physical examination disclosed moderate arteriosclerosis only.

The disagreeable, sometimes very severe, aching pain in the fingers of sufferers from *Raynaud's disease* when exposed to cold is due partly to nutritional changes and areas of necrosis in the fingers and partly to the sudden release of warm blood into chilled fingers which follows the release of arterial spasm (Lewis, 1936). *Exquisite local tenderness* is often associated, and can be so intolerable that it will reduce a man to a state of quivering sobs. Lewis disproved the earlier conception that arterial spasm was the cause of the pain in this condition, for, although digital arterial spasm accompanies every attack, pain is not complained of in the more benign cases of *Raynaud's disease*.

The *glomus tumour* is a more uncommon lesion but is clinically important because of the paroxysms of pain which it produces. It consists of a benign hypertrophy of the microscopic arteriovenous capillary anastomoses which exist in the skin, chiefly of the pulp and nail-bed of normal fingers (Masson, 1924), and in health probably subserves the function of controlling skin temperature. The *glomus tumour* appears as a small slate-blue elevation on the skin, though if subungual in position it may not even be visible, and its most discriminative feature is the agonizing pain which the patient feels on the slightest pressure, friction, or exposure to cold. Now and then localized erosion of the terminal phalanx can be demonstrated by radiographs. The rich supply of nerve fibres which terminates about the epithelioid cells that comprise the vascular spaces of the glomal body would seem to be unduly sensitive to changes in vascular tension and so account for the inordinate pain which simple manipulation produces. These tumours may be single or multiple, and vary in size from a pin's head to a cherry stone. Surgical excision is usually curative.

Abdominal Pain

Aneurysm of the abdominal aorta was stated by Osler (1905) to be seven times less common than thoracic aortic aneurysm. Improvements in antisyphilitic therapy and an increasing average age of the population are modern factors which have probably diminished this ratio, so that the present picture has somewhat altered. Aneurysm of the abdominal aorta seldom arises before the age of 50, and is generally arteriosclerotic in origin. It is said to provide some of the most varied and dramatic pictures seen in clinical medicine (Jennings, 1941). The "dull, boring, steady pain with awful paroxysms," wrote Stokes (1854), "enables us to diagnose the disease with probable accuracy." The pain, he observed, could be relieved by lying on the face or turning on the side. The following personal case would appear to be an example of this condition.

A housewife, aged 72, complained of a throbbing, aching sacral pain of six months' duration, eased by walking about and made worse when she sat on a chair or lay down. She also stated that her feet had always felt cold. The only significant clinical finding was weak pulsation in the arteries of the left leg, but x-ray examination showed a calcified abdominal aorta of irregular calibre. Physiotherapy has not affected her symptoms.

In these instances the pain may be due in part to bony erosion of the vertebral column, yet it is interesting to note how, owing to their resilience, the intervertebral disks often resist. Palpation of the abdomen perhaps discloses a fixed, expansile, tender, pulsating tumour, maybe with a murmur heard or a thrill felt over it. The epigastric pulsation of an enlarged right ventricle must not be confused with an aortic

aneurysm—the systolic thrust of the latter comes appreciably after the ventricular pulse—or with the symptomless dynamic pulsation of a normal aorta which is so easily demonstrated in the patient with a scaphoid abdomen and exaggerated lumbar lordosis, particularly if there is nervous overaction of her heart. Although an aortic aneurysm may rupture several months after the pain first appears, the prognosis is very often better, depending on the location and size of the aneurysm. Rupture is not always fatal.

Dissecting Aneurysm

During the last 25 years at Westminster Hospital there were 26 deaths from this cause, giving an incidence of 1 in 152 necropsies (Pulvertaft, 1949, personal communication). Elsewhere the necropsy incidence has been 1 in 430 (Glendy *et al.*, 1937) and 1 in 454 (Warren and McQuown, 1948). Although clearly a rare and often fatal condition, the number of cases diagnosed during life is steadily increasing, and we now realize that survival for some years may be possible, especially when re-entry of the dissection takes place into the original aortic lumen.

The important clinical feature to recognize is the dramatic suddenness of the onset of the pain and its initial overwhelming severity. Tearing, stabbing, choking pain strikes the patient usually across the chest and arms, but may spread to the back and down the abdomen to the labia or testicles, later to the legs. It may be intermittent and disappear gradually, to recur in subsequent attacks at lower levels as the dissection extends. Unlike the pain of cardiac infarction it is singularly maximal at its onset: a sense of constriction is unusual, hypertension is invariably present, and the dissection commonly begins during an act of physical exertion or sudden emotional strain. Severe pain in the back or spine indicates splitting up of the walls of the descending aorta, with rupture of the intercostal and lumbar arteries (Shennan, 1934). The dissection may obliterate the coeliac axis to cause infarction of the bowel, or the renal arteries may be involved.

From a detailed study of 28 cases Shennan decided that the essential aetiological lesions in this condition were multiple faults in the aortic media, which were filled with homogeneous connective tissue. Contrary to the common belief, the development of aortic dissection by penetration of the blood into the wall of the vessel through the base of an atheromatous plaque is extremely rare. The fact that the intima was sometimes intact suggested that haemorrhage might originate from the vasa vasorum.

In the symptomatology of *mass thrombus of the left auricle*, which occurs in certain cases of mitral stenosis, Evans and Benson (1948) point out that attacks of anginal pain in the chest are usual.

A woman, aged 57, with mitral stenosis and fibrillation, whom I have at present under observation, was seized with sternal pain for 12 hours: next day she developed an equally severe pain in the back and right loin. Her blood pressure was normal. The whole sequence of symptoms, from which she eventually made a good recovery, was at the time striking enough to invite possible confusion with dissection of the aorta, yet the aetiology was probably mass thrombus causing acute coronary insufficiency, followed by a small right renal infarct.

Embolie or Thrombotic Occlusion of the Aorta

In a patient with long-standing rheumatic mitral stenosis and fibrillation, or with a past history of coronary thrombosis, the onset of an abrupt, sharp, intense, and agonizing pain in the legs, loins, abdomen, or back, followed by shock, loss of power, and gangrene, with absence of pulsation in the abdominal aorta, suggests embolism at the aortic bifurcation (Morest and Rubin, 1948). Multiple viscer

embolic incidents may have preceded or may accompany it. Thrombosis of the aorta, on the other hand, is characteristically of gradual onset and develops usually in an arteriosclerotic subject; it is often preceded by symptoms of claudication in the legs (Banowitch and Ira, 1928). These features are illustrated by the following case.

A stock foreman, aged 50, with 2½ years' history of bilateral saphenous thrombophlebitis, followed by a coronary thrombosis and increasing claudication in the right calf, was in hospital for treatment of gangrene of the right big toe. He had clinical signs of generalized arteriosclerosis with an impoverished arterial circulation in both feet. Electrocardiograms showed fibrillation and left bundle-branch block. One morning a month later a mild gripping umbilical pain developed, gradually increasing in intensity. By midday it was severe, and vomiting, bloody diarrhoea, and shock came on. By evening morphine eased the pain, but two days later a sudden haematemesis closed the scene. Necropsy revealed an old apical infarct of the left ventricle with a large mural thrombus. An extensive thrombus occluded the aorta from above the origin of the superior mesenteric to below the bifurcation of the iliac arteries. The whole of the small intestine was infarcted. Atheroma was present in the coronary arteries, aorta, and right popliteal.

From time to time, as in the following case, the pain of a *false aneurysm* presents difficult diagnostic features.

An ice-cream manufacturer, aged 26, with a history of previous rejection for military service because of a rheumatic heart, developed a septic rash and fever. Three weeks later, when admitted to hospital, the blood culture yielded haemolytic *Staphylococcus aureus*; penicillin therapy was started at once (500,000 units a day).

On examination there was a loud apical systolic murmur and a mitral diastolic murmur. Rhythm was regular. After three weeks the fever was still present, so the penicillin dosage was doubled. He now began to complain of a series of pains which baffled his physicians, though admittedly examination was always difficult because he was a grossly obese and excitable subject: first a severe suprapubic pain with vomiting; five days later acute cramping pain in the right leg, yet without any unusual physical signs. Three weeks later he had an intense pain in the right groin, with shock, and developed signs of psoas irritation. Rectal examination was negative. A week later, with groin pain and thigh flexion continuing, thrombosis became evident in the right saphenous vein, and within a few days his leg was oedematous. Although he repeatedly complained of a great deal of pain throughout the next few weeks, his temperature fell to normal, and a non-tender cord-like thickening of the vein in the groin could then be made out. Three months after admission he became suddenly breathless with pain in the chest; anuria set in, and in forty-eight hours, with signs of a left lung infarct, he succumbed.

Necropsy showed that his attacks of pain had been due to a false aneurysm of the pelvic vessels, probably mycotic. A blood cyst the size of a large grapefruit lay against the right brim of the pelvis, containing laminated clot and compressing the right common iliac artery and vein. Venous thrombosis extended down the veins in the thigh and up the inferior vena cava to the right renal vein. Old infarcts were present in the right kidney. In the heart the left ventricle was considerably hypertrophied, and the aortic cusp of the mitral valve contained a perforation ¼ in. (1.9 cm.) in diameter surrounded by healed vegetations. The upper lobe branch of the left pulmonary artery was occluded by recent thrombotic embolus.

Pain in the Legs

The uncomfortable, continuous, aching pain that arises in the calf of the healthy leg when walking fast in tight puttees, or in the shin when bicycling hard or skating, is identical with the pain of *intermittent claudication*. It is produced by a relative ischaemia of the working muscle. There are, indeed, many pathological processes in which this disproportion between the blood requirement of the leg and its blood supply is enough to induce such a pain,

but the commonest is *obliterative arterial disease*. Claudication is an occasional symptom of *severe anaemia*, *aortic stenosis*, *arteriovenous fistula*, *coarctation*, after *aneurysm thrombosis*, or *embolism* of the *femoral* or *popliteal* artery, in some cases of *mitral stenosis*, and, rarely, in a prolonged attack of *paroxysmal tachycardia*. The pain is described as cramp-like only because of its resemblance to the pain of muscle cramp, for tonic spasm of the ischaemic muscle does not in fact take place.

The reason why the effects of arterial obstruction by intravascular thrombus are more profound than simple ligation is because the collateral vessels are usually already diseased and clotting is often extensive, obliterating the mouths of many collaterals.

An office worker, aged 49, for five months had a localized pain in the right calf on walking, which had gradually become so severe that slow walking for 100 yards brought it on and made him stop to obtain relief. Skin temperatures of the feet were normal, but pulsation in the right popliteal, tibial and dorsalis pedis arteries was reduced. Arteriograms showed an obstruction in the middle of the femoral artery with collateral channels. He was operated upon and 4.5 cm. of the right femoral artery excised; this contained organized thrombus on an atheromatous plaque. The vessel was reconstituted with a portion of saphenous vein from the left leg and joined by vitallium tube. A month later, although he still had no palpable pulse in the right foot, he was able to walk a mile without pain.

Many patients such as he provide a clear enough description of their symptoms to make recognition easy, but it may be remembered that various orthopaedic conditions give rise, on using the limb, to pain which is also eased by rest. It will be noted, for example, that the pain of arthritis is not relieved by simple halting, but that the patient has to sit down to be relieved of it. Exercise tolerance in claudication relates to the extent of the arterial disease, frequently an asymmetrical process: so it happens that pain in the worse limb may restrict walking before the sounder limb is fully tested. Similarly, an advanced degree of arterial insufficiency in both legs can be masked by a limitation to the capacity for exercise which angina or dyspnoea may impose; the converse is also true. In arteriosclerosis obliterans the reduced blood supply to the limb sooner or later causes coldness in the foot, and the toes are often cyanosed. The skin may undergo further trophic or inflammatory changes as a result of damage by cold, and become glossy, telangiectatic, and unduly sensitive to warmth and friction. In these circumstances pain is felt *at rest*.

A clerk, aged 71, for two years complained of pain in his calves which pulled him up after five minutes' walking. Resting eased it at once. For the previous nine months he had also had constant pain in the toes of the right foot—"They burned in bed at night"—so that he was obliged to hang his foot out in the cool air or stand up by his bed to obtain relief. The toes were cold and plum-coloured, and arterial pulsation was absent from both feet.

In cases of rest pain the simple correction of a bed whose mattress sags in the middle may prevent some postural ischaemia of the feet.

The third variety of pain in arteriosclerotic disease of the lower limbs is that of *gangrene*. When the vitality and healing power of the tissues is so reduced that infection and necrosis may proceed unchecked, gangrene starts readily from a superficial abrasion, a corn, or a damaged toenail. Pain may be extreme. Lewis's advice to care for the feet as though they were pieces of porcelain cannot be given early enough to sufferers from this complaint.

With *arterial embolism* the dramatic onset of a sudden severe pain in the leg, becoming more intense, aching, and

fluse, usually precedes the other signs. Lewis (1936) has pointed out that this pain does not arise in the artery at the site of the obstruction but much lower in the limb in the muscles deprived suddenly thereby of their blood supply, and that its onset even when abrupt is delayed. It is relative in severity to the size of the occluded artery chiefly because a greater territory of tissue is rendered ischaemic, and it is relieved instantly when the blood supply is restored by removal of the clot, or it is reduced in degree if the plug passes on. Thus embolism of the main or spleen is painless, because those organs contain no muscle. There is no evidence that arterial spasm alone directly produces pain.

The clinical associations of embolic catastrophes are well illustrated by the following case.

A man aged 38, who eight years previously was found to have mitral stenosis, developed auricular fibrillation and at the same time a sudden (painless) right hemiplegia due to cerebral embolus. Two years later his digitalis was inadvertently stopped for a while and his heart began to race. Ten days after redigitalization he woke with a violent pain in the hemiplegic leg and the foot went cold. The agony of his pain lasted twenty-four hours and was relieved only by hanging a tin fast down. From 4 in. (10 cm.) below the knee his leg as found to be cyanosed, oedematous, and icy cold. The agnosia of popliteal embolus was made and he was treated unsatisfactorily. Within ten months he could walk unaided for 10 yards without pain, but four months later he suffered another stroke and died.

Tragic examples of this nature are only too common here embolic incidents have accompanied the onset of fibrillation or have followed mistakes in treatment. Because the pulse rate is slow or the symptoms have abated, digitalis maintenance therapy is stopped; the insidious acceleration of the ventricular rate which ensues is fraught with dangerous consequences. Such accidents would happen so often if we always remembered to warn each patient with auricular fibrillation that digitalis was his life-line, to be depended upon perpetually for the rest of his days.

Conclusions

In those circulatory conditions where a prevailing symptom is extrathoracic pain (in the head, limbs, or body) the regenerative arterial disorders play an important part with their attendant thrombotic and embolic incidents. Hence the symptom of extrathoracic pain in cardiovascular disease or the most part is rare in childhood, unusual in youth, and commoner as age advances. The pain usually conforms to some distinctive clinical picture. Examples are considered in this paper with the object of promoting familiarity with their qualities.

VIOFORM IN THE TREATMENT OF SKIN DISEASES

BY

I. MARTIN-SCOTT, M.D.

The quinoline derivative known as "vioform" (5-chloro-7-iodo-8-hydroxyquinoline) is a stable, almost odourless, greyish-yellow powder which is only slightly soluble in water. It contains 41% iodine and 12% chlorine, and its use in the treatment of amoebiasis is world-wide (Cameron, 1947). For several decades it has been used as an antiseptic dusting powder and as the active ingredient of Alexander's ointment on the Continent (Perutz *et al.*, 1933). Only within recent years has its value in dermatology been appreciated in America (Wise and Sulzberger, 1942; Sulzberger and Wolf, 1942; Pillsbury *et al.*, 1943), and the external therapeutic uses were recorded by the American Medical Association in 1944. In Great Britain its value in dermatology has not yet been estimated.

Early in 1948 I obtained a small quantity of vioform powder and, in a 3% strength in a water-miscible cream, found it to be most useful in the treatment of pyococcal skin infections. The importing chemists then kindly offered to manufacture two types of preparation for trial, and a clinical investigation was started in June, 1948.*

Preparations Used.—Guided by the experience of Sulzberger and Baer (1946), it was decided to use only the following two preparations: (1) vioform cream (V.C.), which consists of 3% vioform in a water-soluble base composed of sodium lauryl, stearyl alcohol, spermaceti, glycerin, yellow soft paraffin, and water; (2) vioform ointment (V.O.), consisting of 3% vioform in a simple petroleum-jelly base.

Selection of Cases.—The majority of the cases were treated as out-patients. The greater number and variety of such cases outweighed the uncertainty of proper application by the patient. Patients of any age or sex were treated, but in view of the limited supplies of vioform no cases of widespread dermatoses were included. With the knowledge that other hydroxyquinoline ointments were useful in the management of pyoderms, it is not surprising that many cases of this type were chosen.

Control of Results.—It was considered that the number of cases would be too small to compare this remedy against a standard topical treatment by the method of treating alternate cases suffering from the same skin disease. Likewise, the better method of comparing the results of two similarly affected and symmetrically situated lesions in the one person treated by two different methods was thought impracticable in dealing with out-patients. Where it is considered to be of interest, however, reference will be made to previous treatments which had failed.

Classification of Cases.—A total of 115 consecutive cases of various skin diseases were treated. These have been grouped thus:

Group A	..	Sycosis barbae	15 cases
" B	..	Folliculitis of other areas	17 "
" C	..	Impetigo contagiosa	14 "
" D	..	Acne vulgaris	10 "
" E	..	Impetiginized eczema	14 "
" F	..	Post-auricular dermatitis	10 "
" G	..	Miscellaneous group	35 "

Where more than one type of infection was present the case was listed under the more prominent condition.

*I am indebted to Messrs. Ciba Laboratories, Ltd., Horsham, Sussex, for kindly supplying the applications used in this study.

Results of Treatment

Group A. Syccosis Barbae

The patients were instructed to use V.C for shaving, and to leave a film on the face thereafter. A second application was advised at midday, and V.O was used at bedtime. They were told that this was a treatment under trial, and all promised to report any relapse which might occur.

TABLE I

Table I shows that 13 out of the 15 cases had no signs of active disease after treatment with vioform alone. Only two of these 13 cases had slight relapses, which quickly responded to further treatment. The average treatment time of the 11 cases which were apparently cured after one course was three weeks, and the average duration of the disease before treatment was over 2½ years.

With such a short follow-up period it cannot be claimed that 87% of the cases were "cured." It will be noted that four of the cases failed to report back after apparent cure. These cases may be considered to have remained free from symptoms for the following reasons: (1) three of them had suffered for several years and had been "cured" in a few weeks; (2) vioform preparations could not be renewed without further consultation and were not yet on sale to the public, and (3) three of the cases lived in a country district served by one local hospital.

The only two failures were Cases 37 and 74. The former patient volunteered that it was "easily the best stuff" he had used in his three years of treatment. In both cases the lesions were indurated and deep-seated, and the pus was caseous. Case 74 was eventually cleared up by cauterizing the four remaining pustules with pure phenol, and Case 37 is at present having fractional doses of X rays in conjunction with vioform treatment.

It is of interest to note that twelve of these cases had previously been treated unsuccessfully with local penicillin, and that in four of these the causative *staphylococcus* was found to be penicillin-sensitive.

Table II shows that all 17 cases responded well to treatment. The average duration of treatment was just under three weeks, but this includes two cases which required six weeks, these two cases were infections of the forearms

Group B: Folliculitis of Other Areas

TABLE II

The results in all cases were good, and no relapses have been reported (Table III). In no case was any additional application used to remove infected crusts. Six cases in which the organism cultured was reported to be penicillin-sensitive failed to respond to local penicillin therapy. In many cases the patients claimed to be cured in two to three days, and the duration shown in Table III was the time interval till the patient was actually seen to be cured. Even with this possible overestimation the average treatment time for all types was only 10 days.

Group D: Acne Vulgaris

Ten cases of pustular acne were treated, and only five showed some slight improvement after four weeks of VC

daily. The results were not impressive, as it must be remembered that, while vioform was the only local application, the patients were advised regarding general hygiene diet, and in several cases oestrogens and/or vitamins given simultaneously.

formerly used "ung. quinolor co." (Squibb) in cases of pustular acne with decidedly better results, possibly due to the benzoyl peroxide content in this preparation.

Group E: Impetiginized Eczema

There were 14 cases of eczema (mostly exogenous) which had become secondarily infected, and all presented crusted scaly lesions. In two-thirds of the cases the hands and fingers were affected. The more exudative cases were treated with V.C. thrice daily, while the other half applied O. twice daily. In the four cases investigated *Staph. pyogenes aureus* was cultured. The average duration of treatment was just over two weeks, and during this time the treatment was sheltering the affected area from external irritants. The underlying eczema was cured in only two cases, but in all cases the crusting and inflammation subsided satisfactorily.

Group F: Post-auricular Dermatitis

TABLE IV

Case No.	Sex	Age	Duration of Disease	Previous Treatment	Bacteriology	Prep. Used	Time to Effect Cure
8	F	44	6 weeks	G.V., Pen.	S.P.A., Str. haem. A.	V.C.	2 weeks

11	F	32	3 weeks	Hg	S.P.A.	V.O.	1 week
17	M	45	2 months	Ung. S. & S.	Str. haem.	V.O.	1 "

Pen. = Penicillin preparation. S.P.A. = *Staph. pyogenes aureus*. Str. haem. A. = *Str. haemolyticus* Group A. Hg = A mercury preparation. AgNO₃ = Silver nitrate lotion 1%. G.V. = Gentian violet lotion. Ung. S. & S. = Ung. sulphur id salicylic acid B.P.

Every case had associated seborrhoeic eczema, and two ad menopausal symptoms. Clinically the skin behind the ears was found to be reddened, glazed, and often exuding serum. The response to treatment was very good, and the average treatment time was just over two weeks. No relapses have been reported (Table IV).

Group G: Miscellaneous

This group comprises a miscellaneous collection of dermatoses which are often rather resistant to treatment. There were 35 such cases.

Angular Stomatitis.—Four of the five cases treated with V.C. twice daily cleared up after an average treatment time of 10 days; no other therapy was given simultaneously. In two of the cases there was associated naso-labial fissuring, which also responded well. The one failure is discussed later when dealing with toxicity.

Intertrigo.—There were five cases, which occurred in elderly patients. Clinically they did not suggest a fungal infection. The apposing skin surfaces were red and denuded, and in the midline there was often some superficial fissuring. Three of the five cases were considerably improved after four weeks' treatment with V.O.

Furunculosis.—Three of the four cases had suffered from recurrent boils for many years. In all four the septic conditions were cured within two weeks, but fresh boils occurred in two. These cases were found to have high fasting-blood-sugar levels, and when suitably dieted had no further furunculosis.

Chronic Paronychia.—Two of the four cases treated showed the typical chronic bolstering of the nail-folds, with dystrophy

of the nails but no purulent discharge. Staphylococci were cultured in both cases, and after four weeks' treatment they showed considerable improvement. The other two cases had purulent lesions of the nail-folds from which *Staph. pyogenes aureus* was cultured; there were no whitlows. Both cleared up after applying V.O. for an average treatment time of three weeks, though they had been resistant to local penicillin treatment.

Septic Excoriations.—Two cases of generalized pruritus and one of excoriated acne were treated. V.O. cleared up the crusted lesions in a short time but did not lessen the pruritus.

Chronic Lichen Simplex.—Two cases of localized lichenified skin without any associated infection were not improved by the use of V.O., nor was the irritation lessened.

Pruritus Ani.—One case, in which no changes in the skin could be seen, failed to be relieved after four weeks on V.O.

Pustular Psoriasis.—Three cases of the toxic bacterioid type, with small intra-epidermic lakes of pus and light-brown punctate scabs affecting the soles and palms, were not improved after several weeks' local treatment with V.O.

Pustular Epidermophytosis.—Two cases of secondarily infected epidermophytosis interdigitalis in which *Staph. pyogenes aureus* was cultured from the pus, but in which there was no acute pain or lymphangitis, were treated. All evidence of sepsis had gone when seen 14 days later.

Ulcers.—Two simple chronic ulcers of obscure origin, one of the chin and one of the thigh, were slightly improved after dressings with V.O. twice daily.

Acne Necrotica.—One case showed improvement after treatment with V.O., but was not cured.

Furfuraceous Impetigo.—One case of four years' duration showed no significant improvement after four weeks' treatment on V.O.

Herpes Zoster.—This patient was an elderly man who was febrile and had a large crusted plaque over the frontal region. *Staph. pyogenes aureus* was cultured. He was treated with V.C. thrice daily, and within one week all evidence of infection had gone.

Pemphigus Vulgaris.—In one case V.O. was found to be a useful antiseptic dressing which assisted the healing of the raw areas after rupture of the bullae.

Mode of Action; Toxicity

Animal experiments in the past (Ciba, Ltd., 1948) and also the following observation on a patient have failed to support the theory that the disinfecting action of vioform is due to the liberation of free iodine. A patient who had a severe contact dermatitis due to tincture of iodine and who reacted with an extensive vesicular eruption to painting 1 sq. in. (6.45 cm.²) of her arm with liquor iodi mitis had no reaction after 48 hours' contact with 3% V.O.

About 5% of the patients treated admitted that there was a mild initial stinging of short duration, but in none of these cases was treatment discontinued.

In only one of the 115 cases was there severe primary irritation when V.O. was applied to the diseased skin. This patient was a nervous man who had had a long history of sycosis barbae, and his clinical record indicated that he was sensitive to sulphathiazole and "elastoplast." He reported with a slight angular stomatitis and erythema, scaling, and fissuring of the naso-labial folds. He was advised to apply V.O. twice daily to the affected areas, and when he reported two weeks later the condition was unchanged and he complained of intense irritation on each application of the ointment—he had stopped using it after only ten days. V.C. was applied in the consulting-room and he complained of irritation, though no inflammation was noted after 40 minutes. A patch test of V.O. applied to the healthy skin of the arm was negative after 48 hours. This is similar to the case of irritation reported by Reque (1947) in which true epidermal sensitivity was also absent. It seems probable that in my case the irritation was due to the vioform and not to the

paraffin base, as he subsequently improved on ung. hydrarg. ammon. dil.

Saunders (1946), who used vioform 1% in petrolatum in a mixed series of 14 cases, did not attempt any further study of the medication, because the incidence of irritation was too high and the beneficial results too poor.

No systemic toxic effects due to absorption from the skin were encountered. In view of the internal use of "enterovioform," this was not surprising.

Comment

In a study of a comparatively small number of cases in which the results of treatment were not controlled it is not possible to evaluate the efficiency of vioform scientifically. The clinical impression, however, in the management of several dermatological problems was extremely good. The ability to confront the chronic case of sycosis barbae and persistent post-auricular dermatitis without foreboding signifies at least the possession of a therapeutic agent of prowess. A safe and relatively non-irritant antiseptic or antibiotic is always welcome in dermatology; thus penicillin became the practitioner's friend. Later many pyococci were found to be resistant to it. It is probable that since the introduction of penicillin the number of skin infections referred to hospital has diminished—e.g., no cases of impetigo of children's faces have been seen in the last six months for inclusion in this series. No doubt the proportion of penicillin-resistant cases seen in hospital has increased. Whether vioform is superior to penicillin in the treatment of pyodermias cannot be assessed from this report, but it is a fact that in at least 37 cases in which penicillin had failed vioform produced the desired result. In the 16 cases in which penicillin sensitivity was estimated four were resistant and 12 were sensitive to penicillin. In 11 of these 12 cases penicillin had previously been used and had failed to improve the skin infection.

Summary and Conclusions

The value of 3% vioform in an ointment and in a cream base has been studied in 115 dermatological cases.

The results indicate that vioform is a valuable therapeutic agent in dermatological practice, and particularly in the treatment of pyococcal skin infections such as impetigo, folliculitis (especially sycosis barbae), impetiginized eczema, angular stomatitis, and post-auricular dermatitis. The cases of acne vulgaris in this series were not greatly improved.

It is relatively non-irritating, and the occurrence of epidermal sensitization is rare.

While it relieves the prickling of infected eczemas, it does not seem to have any antipruritic effect on non-infected dermatoses.

The only slight disadvantage revealed was the yellowish-grey colour. The cream is easily washed out of cotton fabrics, but stains from the use of the ointment are more difficult to remove.

Further study is required to estimate its value in other vehicles in dermatology, and also in other branches of medicine where antiseptic applications are required.

It is concluded that 3% vioform is a valuable addition to the medicaments at present used in this country for pyococcal dermatoses.

THE TOPICAL USE OF VIOFORM IN DERMATOLOGY

BY

JAMES OVERTON, M.D., B.Sc., M.R.C.P.

Honorary Chief Assistant, Skin Department,
Leicester Royal Infirmary

The present investigations have been prompted by the shadow of Nemesis which now looms on the dermatological horizon, threatening retribution, in the forms of drug sensitization and drug-resistant organisms, for the indiscriminate topical use of sulphonamides and antibiotics. A spate of literature has indicated that drug sensitization may follow the external application of sulphonamides (*Army Med. Dept. Bull.*, 1943; Barber, 1944; MacKenna, 1945; Phillips, 1946; Tzanck *et al.*, 1947; Council on Pharmacy and Chemistry, 1947) and penicillin (Canizares, 1945; Friedlaender *et al.*, 1946; Chu and Cutting, 1946; O'Donovan and Klorfajn, 1946; Goldman *et al.*, 1946; Hellier, 1947; Templeton *et al.*, 1947; Phillips, 1948) and so seriously interfere with their later use in lethal disorders. Drug resistance, a sequel of sulphonamide therapy and the use of many antibiotics, has been shown by Barber (1947) and Barber and Rozwadowska-Dowzenko (1948) to occur when penicillin is used; their work foreshadows many more strains of penicillin-resistant *Staphylococcus aureus*.

My attention was directed by the work of Ingram (1938) and of Sulzberger and Wolf (1942) to an entirely different group of drugs—namely, the halogen-substituted quinolines. An attempt has been made to assess whether these drugs may be used to replace the sulphonamides and penicillin in external applications so that the aforementioned undesirable sequel may be avoided. The two members of this group under investigation are "vioform" and "sterosan." This paper deals with the former drug only.

Quinoline derivatives have been used for topical application in dermatology for a number of years. "Ung quinolor co." (Squibb) contains a mixture of 5-chloro-8-hydroxyquinoline, 7-chloro-8-hydroxyquinoline, 5:7-dichloro-8-hydroxyquinoline, together with 10% of benzoyl peroxide in a paraffin-lanolin base. It is useful in the treatment of sycosis barbae, impetigo contagiosa, eczematized psoriasis, and psoriasisiform or lichenoid neurodermite (Peck, 1934; Carpenter, 1938; Ingram, 1938).

Vioform has the chemical formula: 5-chloro-7-iodo-8-hydroxyquinoline.

It is an amorphous, greyish-yellow, voluminous powder containing 41% of combined iodine. Tasteless and colourless, it is insoluble in water and only slightly soluble in alcohol. It has a melting-point of 156° C. and can be sterilized at 100–110° C. Light and moisture cause a darkening in its colour. Oxidizing agents are chemically incompatible.

Pharmacology.—Widespread oral use of the drug for amoebiasis has shown that it is relatively non-toxic in man (David *et al.*, 1944). *In vitro* it inhibits *Staph. aureus* and *Bact. coli* in a dilution of 0.025%, and *Pseudomonas pyocyanea* in a dilution of 0.5%.*

Mechanism of Action.—Repeated experiments have been performed to ascertain whether the antiseptic action of vioform is due to the liberation of iodine. The investigations reveal that iodine can be liberated only with great difficulty, and that free iodine plays little or no part in its antiseptic action (Bachem and Kriens, 1921; Chargaff, 1929; Jadassohn and Planer, 1945).

Clinical Application.—Vioform has been employed on the Continent for the last forty years, and its virtues have been extolled in the treatment of pyoderma, fungous infections, eczematous conditions, and other dermatoses (Jadassohn, 1930; Berlich, 1939; Sulzberger and Wolf, 1942). Montigel (1910) found it a more effective antiseptic tooth-stopping dressing than iodoform. Sulzberger and Wolf (1942), after extensive clinical trials, stated it to be "one of the best anti-eczematous, mildly soothing, and antiparasitic remedies."

Types of Bases Employed and Mode of Application.—Vioform was used in this trial in a strength of 3% in a water-miscible cream† and a soft paraffin ointment. An identical cream and ointment, suitably coloured to camouflage the absence of vioform, were used as controls.

The type of application employed was determined by the characteristics of the lesions. The cream was mainly used to produce a drying effect; in dry, scaly, or lichenified lesions the greasy ointment was prescribed. Occasionally a more neutral effect was obtained by alternating the two, using the cream by day and the ointment by night. The cream was applied three or four times a day, the lesions being kept open wherever possible. The ointment was applied twice a day, and in view of its greasy staining qualities was covered with linen or calico. No other local measures were in use at the same time.

Mode of Assessment.—The only cases included in this series are those which have been adequately controlled by using the active preparation on one side of the body and a control (the ointment or cream base) on the other side. By this means spontaneous improvement becomes evident, the effect of the conveying medium is readily assessed, and aggravation by the active ingredient is apparent, except where the base itself proves irritant, thus sometimes masking any similar action of the drug concerned. Unfortunately, some disorders do not admit of this simultaneous assessment—e.g., pruritus ani—and these have been omitted. The major practical difficulty lies in persuading the patients to adhere strictly to instructions in spite of any difference in response on the two sides. Results were assessed only in terms of visible improvement.

Results

Group 1: Coccogenic Sycosis Barbae.—All these cases had received previous treatment, many with penicillin cream or ointment. A number were chronic cases complicated by seborrhoea oleosa. All were investigated for focal sepsis, and this when found was treated simultaneously. Patients were instructed to shave daily and to apply the cream after shaving, at midday, late afternoon, and night. The face was washed in the normal manner. Among 30 cases, 22 showed a definite improvement, 3 chronic cases

Table of Results

Diagnosis	Total No. of Patients Treated	No. of Patients Affected by Vioform		No. of Patients Affected by Control Base		No. of Patients who Showed no Response to Vioform or Control Base
		Improved	Aggravated	Improved	Aggravated	
Coccogenic sycosis barbae	30	22		1		7
Seborrhoeic dermatitis	22	14		5		3
Otitis externa	14	8		4		2
Pityriasis faciei simplex	2	2				
Acute vesicular and papular eczema	33	15	1	10	2	5
Gravitational eczema	18	12		4		2
Cheirropompholyx	13	3	1			9
Chronic papular and fissuring eczema	7	1				6
Impetigo	5	5				
Infantile eczema	16		3	8		5
Nummular eczema	7	4	2		1	
Neurodermatitis lichen hypertrophicus	5	1	1	3		
Psoriasis: Classical	2					2
Seborrhoeic	6			1		3
Pustular	2			2		
Dermatitis herpetiformis	4		1	2	1	

improved temporarily and then relapsed during treatment, 1 showed equal improvement on the base, and 4 exhibited no gross change.

Group 2: Seborrhoeic Dermatitis.—These represented typical examples of the disorder with lesions in the scalp, on the face and ears, and in some cases on the trunk as well. Many of the facial lesions were eczematized. The scalp was treated in the routine manner, the vioform application being used only for the face. Of 22 cases, 14 showed a marked improvement, 5 improved equally on both sides, and 3 showed no change.

Group 3: Otitis Externa.—This group was mainly composed of patients exhibiting the signs of streptococcal otitis externa as described by Kinnear and by Mitchell. In a few the external manifestations followed an attack of suppurative otitis media, and some had a superimposed contact dermatitis. A search was made for evidence of focal infection, and where necessary this was treated. Among 14 cases, 8 showed marked improvement, 4 equal improvement on both sides, and 2 no change.

Group 4: Pityriasis Faciei Simplex.—The two children suffering from this disorder made a slow response.

Group 5: Acute Vesicular and Papular Eczema.—This comprises a mixed group of endogenous and exogenous eczema, comparable in the appearance of their eruptions. They were usually given sedative treatment by mouth. Fifteen patients showed much improvement on the vioform preparation, 10 responded equally to the vioform and the control preparation, 2 were aggravated by both, 1 improved more rapidly on the control cream than on the vioform cream, and 5 showed no improvement on either side.

Group 6: Gravitational Eczema.—Among these patients suffering from bilateral gravitational eczema without active ulceration, 12 showed much improvement, 4 equal improvement on both legs, and 2 no change.

Group 7: Cheirropompholyces.—These were all of constitutional origin. Three appeared to improve more rapidly on the vioform preparation, 1 appeared to be aggravated, and in 9 the course of the disorder was unaffected on either side, spontaneous remissions and exacerbations occurring. Concurrent sedation by mouth was used in this group.

*Information supplied by Messrs. Ciba, Ltd.

†This was supplied by Messrs. Ciba Laboratories, Ltd., and was stated to contain sodium lauryl sulphate, stearyl alcohol, spermaceti, glycerin, soft yellow paraffin, and water.

Group 8: Chronic Papular and Fissuring Eczema.—These were 7 chronic cases of endogenous eczema. One showed some improvement, the remainder no change.

Group 9: Impetigo.—Five cases cleared satisfactorily with vioform cream.

Group 10: Infantile Eczema.—The results of the treatment of this condition were unsatisfactory. Eight cases improved equally on the cream and on the cream base, 5 showed no change, and 3 displayed some irritation on the vioform cream.

Group 11: Nummular Eczema.—Four showed marked improvement; two appeared to be irritated by the vioform and one by the cream base.

Group 12: Neurodermatitis.—One showed improvement, three showed equal improvement on both preparations, whilst in one patient the base proved the more effective.

Group 13: Lichen Hypertrophicus.—In three patients no change was noted.

Group 14: Psoriasis.—In two patients with classical psoriasis no improvement could be attributed to the vioform. In psoriasis involving the flexures (seborrhoeic) two appeared to be improved, and four showed no change which could be attributed to the vioform. Two patients with pustular psoriasis found the active preparation and the vehicle equally effective.

Group 15: Dermatitis Herpetiformis.—Lesions in two patients with this disorder responded equally to the vioform cream and base, one patient was aggravated by both, and one appeared to be aggravated by the vioform cream. In view of the sensitivity of these patients to potassium iodide locally, this measure was tried at first very carefully, but the action expected from an iodide preparation was not noted.

Comments

Unfortunately, vioform is yellow and it stains. When dispensed in a water-miscible base the staining tendency is less marked. It darkens on exposure to air; this does not seem to interfere with its therapeutic efficiency. A few patients stated that on application they experienced a mild burning sensation, which quickly disappeared; when there was intolerance this symptom was more pronounced.

Vioform proved antipruritic in eczematous conditions and soothing in the treatment of contact dermatitis; it showed marked antiseptic action in pyoderma and secondarily infected dermatoses. In the media used it was found to be well tolerated.

Conclusions

The effect of 3% vioform in a water-miscible base or in petroleum jelly has been assessed under carefully controlled conditions on a variety of dermatoses in 176 patients. It proved a useful local application in the treatment of the following conditions: coccogenic sycosis barbae, seborrhoeic dermatitis, otitis externa, acute vesiculo-papular eczema, gravitational eczema, impetigo, and, occasionally, in nummular eczema. The incidence of cases of intolerance was low (4.5%). This investigation suggests that vioform merits more extensive use in these conditions.

DISSEMINATED SCLEROSIS IN SOUTH AFRICA

ITS RELATIONSHIP TO SWAYBACK DISEASE AND SUGGESTED TREATMENT

BY

GEOFFREY DEAN, M.B., Ch.B., M.R.C.P.

It has long been believed, and rightly, that disseminated sclerosis very rarely occurs among the white population of South Africa and that it is most rare among those white people who have been born and bred there. Indeed, some physicians deny that it occurs at all in such people. These opinions, however, were based on individual clinical experience; there were no reliable and exhaustive figures. Therefore the available evidence relating to the incidence, geographical distribution, etc., of the disease among white South Africans during the last ten years has been collected and assessed. It may be said here that disseminated sclerosis is unknown in the native and other coloured peoples of the country.

Incidence and Geographical Distribution

In order to discover the incidence, etc., of the condition it was decided to search the medical records of all the main hospitals in the country for the last ten years. Records of a diagnosis of disseminated sclerosis could be found only at Groote Schuur Hospital, Capetown, at Johannesburg General Hospital, and at the Pretoria Hospital—in fact, at the three university teaching hospitals. In addition, three isolated cases—two at Port Elizabeth and one at Durban—have been reported. The cases are here summarized. In all cases, unless otherwise stated, the Wassermann reaction was negative and the blood count normal.

Groote Schuur Hospital, Capetown.—Between 1938 and 1948 eight patients were diagnosed as suffering from disseminated sclerosis. These cases are summarized in Table I. Two of these patients were white women born in South Africa (one lived at Capetown and one at Vryburg); one was a South African who had spent six months abroad; and two others were South Africans of German origin, though in the case of one of these the diagnosis was doubtful. Of the remaining three cases, in one the diagnosis was probably wrong and in the other two the records were incomplete.

Johannesburg General Hospital.—In the files at Johannesburg General Hospital 22 cases were classified as suffering from disseminated sclerosis between the years 1938 and 1948. The cases are summarized in Table II. Five of these patients were indigenous white South Africans, 14 were immigrants, and in the three others the diagnosis was in my opinion definitely

mistaken. These last three cases will not be considered further. Of the five indigenous patients, the diagnosis is considered to be correct in three and doubtful in two.

TABLE I—Cases in Capetown

Case	Sex	Age	Race	Diagnosis
C 1	F	46	S A.	Symptoms of weakness in legs for 20 years, periods of remission; nystagmus, intention tremor, posterior column and pyramidal tract involvement. Seen by me (DS)
C 2	F	40	S A	Symptoms of paraesthesia on trunk, a visual episode, dragging of legs, with remissions, for seven years. Sensory loss, pyramidal tract and posterior column involvement (DS)
C 3	F	35	S A (a)	In England for six months when aged 8. A five-years history, with remissions, of diplopia, tingling in hands, and weakness of both legs. Nystagmus, temporal pallor, and pyramidal tract involvement (DS)
C 4	F	54	IMM	Of German origin. Temporary blindness 20 years ago, tremor, clumsiness, weakness right leg, loss of sensation in foot, remissions. Pallor of temporal half of optic disks; cerebellar, sensory, and pyramidal tract involvement (DS)
C 5	F	30	IMM	Of German origin. Giddiness and anaesthesia of right side of face. On examination no lesion of central nervous system (Doubtful)
C 6	F	47	S A	Twelve years ago had a temporary total paralysis and severe pain affecting both legs, a year later the right arm was similarly affected, a year ago blindness of right eye with pain. No physical signs. (Not DS)
C 7				Case records incomplete
C 8				Case records incomplete

S A = South African white who has never been abroad. S A (a) = South African who has been abroad. IMM = Immigrant. DS = Disseminated sclerosis diagnosed.

Pretoria Hospital, Pretoria—The records reveal one definite case of disseminated sclerosis in an immigrant who entered the country when he was 2 years old, and two doubtful cases (Table III)

Port Elizabeth—Two cases were found here. The first was that of a woman, aged 60, who was born in South Africa but had spent the greater part of her life up to the age of 39 in England. First one eye then the other became affected by temporary loss of vision more than 20 years ago while in England. Since then she had had attacks of weakness in the

legs and arms, with remissions, and hyperaesthesia of the left leg. On examination a classical case of disseminated sclerosis was seen: nystagmus; temporal pallor; and cerebellar, pyramidal tract, posterior column, and sensory involvement.

TABLE III—Cases in Pretoria

Case	Sex	Age	Race	Diagnosis
P 1	M	44	IMM	Immigrated from Australia when 2 years old. In the last nine years attacks of transient blindness and hemiparesis. Nystagmus, intention tremor, ataxia, and pyramidal tract involvement (DS)
P 2	M	53	S A	Fifteen years ago pyrexia and polyarthritides. Agglutinations for <i>Brucella abortus</i> positive. He developed ataxia with nystagmus and Rombergism, is occasionally incontinent of urine, and has transient paraesthesiae. There is pyramidal tract, posterior column, and cerebellar involvement. This seems to be a case of focal demyelination following brucellosis.
P 3	M	59	S A	Account translated from <i>Geneeskundige Tydskrift</i> . Thirty five years ago he had weakness and loss of sensation in both legs, with retention of urine; lumbar laminectomy was performed, a short time later he had double vision for a few days. Six years ago he developed a sudden hemiplegia, since when he has been bedridden. On examination there was right sided hemiplegia with bilateral pyramidal tract involvement, the posterior columns were normal. In my opinion there is not enough evidence to diagnose disseminated sclerosis. The hemiplegia was probably due to a cerebral thrombosis.

The second patient was the brother of the first case. He was also seen by me. He developed a slowly increasing weakness starting at the extremities, over a period of three years; this increased until he died following paralysis of his intercostal muscles. There was a bilateral extensor response, with absent reflexes and slurring of speech. In view of the fact that his sister had disseminated sclerosis this may have been a "forme fruste" of the disease.

Durban—Dr J. Drummond, medical specialist, has informed me that he treated a case of disseminated sclerosis in a South-African-born girl who had not been abroad. Unfortunately the records have been lost, and she has long been dead. As the records are not available, this case will have to be included in the "doubtful" group.

TABLE II—Cases in Johannesburg

Case	Sex	Age	Race	Diagnosis
J 1	M	39	S A	Weakness in right leg, nystagmus, optic pallor, intention tremor, posterior column and pyramidal tract involvement (DS)
J 2	M	40	S A	Unsteadiness of gait, hyperaesthesia of right thigh and weakness of right leg, nystagmus and pyramidal tract involvement (DS)
J 3	F	43	S A	Blurring of vision, paraesthesia, and weakness of both legs, remissions, urinary incontinence. Temporal pallor, intention tremor, sensory loss and pyramidal tract involvement (DS)
J 4	F	17	S A	A two-years history of difficulty with micturition and dragging of feet. No physical signs (Doubtful)
J 5	M	27	S A	Cramp in legs. (Doubtful)
J 6	M	50	IMM	Temporary blurring of vision six years ago, now drags the right leg. Nystagmus, temporal pallor and pyramidal tract involvement (DS)
J 7	M	30	IMM	Loss of sensation in finger tips of right hand drags the right leg, remissions. Sensory loss in fingers and pyramidal tract involvement (DS)
J 8	F	37	IMM	Weakness of both legs and precipitancy of micturition, remissions. Pyramidal tract involvement (DS)
J 9	F	45	IMM	Twenty years ago had temporary blurring of vision in one eye. Weakness in right arm and right leg. Pyramidal tract involvement (DS)
J 10	F	47	IMM	Blurring of vision a few years ago; weakness in right arm and right leg. Nystagmus and pyramidal tract involvement. (DS)
J 11	M	31	IMM	Insufficient details available
J 12	F	31	IMM	Insufficient details available
J 13	M	18	IMM	History suggestive of disseminated sclerosis but details of examination are insufficient
J 14	F	43	IMM	Weakness right leg and difficulty in starting micturition. Insufficient details available
J 15	M	35	IMM	Not disseminated sclerosis
J 16	F	40	IMM	History suggestive of disseminated sclerosis, but details of her physical examination are insufficient for diagnosis
J 17	M	48	IMM	Insufficient evidence
J 18	M	65	IMM	Weakness in both legs and difficulty with micturition. Pyramidal tract and posterior column involvement. W.R. positive. A syphilitic cause for the symptoms has not been excluded
J 19	M	31	IMM	Weakness in left leg. Left Babinski response extensor; W.R. positive. Again a syphilitic cause has not been excluded

Comparison with England and Wales

My opinion, based on the above analysis, is that disseminated sclerosis does occur among South Africans who have never been abroad, but the incidence is extremely low. There have been two cases at Groote Schuur Hospital, Capetown, both women—one who had spent all her life in Capetown, and one from Vryburg—and three cases at Johannesburg General Hospital—one from Lichtenburg, one from Rouxville, Transvaal, and one of unknown address: five cases in all, scattered throughout the Union, and out of a white population of 2,400,000. This number is too small to enable one to draw any conclusions concerning the geographical distribution of the disease. There may of course have been other cases, but an obscure long-lasting disease would usually be discussed by the local doctor and eventually sent to a specialist in one of the big centres; and because of its rarity the specialist would normally send the case to hospital for investigation.

In South Africans who have been abroad two cases were diagnosed at Capetown, five at Johannesburg, one at Pretoria, and one at Port Elizabeth—making nine cases in all (Table IV). Of the doubtful cases in South Africans who have never been abroad there are two at Johannesburg, two at Pretoria, and one at Durban—five in all. There are ten doubtful cases among South Africans who have been abroad—one at Capetown and nine at Johannesburg. Probably the majority of these patients do suffer from disseminated sclerosis. A striking factor about all cases is the mildness of the disease; only one "doubtful" case is bedridden.

It has already been noted that the disease is unknown among the native and coloured peoples of South Africa. Two cases have been reported in East African natives.

TABLE IV.—*Classification of Cases Diagnosed as Suffering from Disseminated Sclerosis in South Africa*

	Capetown	Johannesburg	Pretoria	Elsewhere	Total
Disseminated sclerosis in South Africans who have never been abroad	2	3	0	0	5
Disseminated sclerosis in South Africans who have been abroad, or immigrated	2	5	1	1	9
Doubtful cases in South Africans who have never been abroad	0	2	2	1	5
Doubtful cases in South Africans who have been abroad, or immigrated	1	9	0	0	10

Brain (1940) gives statistics on the incidence of disseminated sclerosis. His figures are for the year 1930. He estimates the incidence as 160 per million for England and Wales. His method of computation, based on that of Bramwell, assumes an average expectation of life of eight years after diagnosis of the condition—in my opinion a very modest estimate. Therefore the annual number of deaths from disseminated sclerosis multiplied by eight million divided by the population is the incidence per million. Later figures give approximately the same incidence. Deaths from disseminated sclerosis in 1935 were 781; in 1938, 764; and in 1945, 760. The population of England and Wales in 1942 was 42,600,000. On the continent of Europe the disease is widespread in Germany, France, Scandinavia, Austria, and especially in Switzerland.

The figure of 160 per million in England and Wales may be compared with the South African figure of five cases out of an indigenous white population of 2,400,000.

Swayback Disease of Lambs

Campbell *et al.* (1947) reported the occurrence of four cases of disseminated sclerosis among seven workers engaged on research into swayback disease of lambs. This is a demyelinating disease, known to be associated with a deficiency of copper in the soil on which the affected lambs are bred, or with a defective absorption of copper.

In order to obtain some information at first hand about swayback disease I visited Onderstepoort Veterinary Research Station and consulted Dr. de Kock, the Director, and Dr. Schultz, one of the research workers concerned with this disease.

Swayback disease is, as far as present knowledge goes, confined in South Africa to three small areas—a small coastal strip around Mossel Bay from Knysna to Bredasdorp, along Saldanha Bay up to Vredenberg, and around Stellenbosch. It will be noticed that the five proved cases of disseminated sclerosis in native-born white South Africans are not confined to these "swayback" areas.

South African farmers call swayback disease "Lamkruis," which means paralysis of the lumbar region; also "Swaai-gat," or swaying back; and "Litsiekte," or joint disease. Adult sheep are seldom affected by it, but newborn lambs commonly are. The incidence is never high, although it does vary from year to year. Affected lambs are unsteady in their gait and spastic in their movements. Post-mortem examination often discloses cavities in the cerebrum filled with a yellowish fluid. The cerebellum is always involved, though there is never cavitation there. Histological examination of the central nervous system reveals a widespread round-cell infiltration and demyelination. Much more detailed work is still required on the pathology and histology of the disease in South Africa.

Relationship between Swayback Disease and Copper Deficiency—For many years the farmers in the "sway back" areas have given pregnant ewes copper sulphate solution by mouth in order to prevent the occurrence of the disease in their lambs. Further, it has been shown at Onderstepoort that there is a relationship between the copper content of the grazing and the presence of the disease. In the Karroo areas, where swayback disease is unknown, the ruminal copper content (which is an index of the copper content of the soil) is 13 parts per million—a high proportion; but in the coastal areas, where the disease does occur, it is only 5 parts per million. This relationship has also been noted in England; and there, too, copper sulphate is given in certain areas to pregnant ewes as a means of prophylaxis against the disease. Less commonly, but successfully, it has been used in the treatment of established cases. A point of interest is that in the Karroo a form of jaundice occurs in sheep, known as enzootic icterus, with gross haemolysis and haematuria. Post mortem, the copper content of the liver is found to be over 200 times the normal. Enzootic icterus seems to be a form of copper poisoning, although why the copper, which is normally fixed in the bones, should be suddenly mobilized is not known. Experiments are now being carried out to find if copper can be mobilized in the same way as lead—by giving acid salts. This research is of particular interest because of the possible toxic results of copper therapy in man.

Relationship between Disseminated Sclerosis and Swayback Disease.—No explanation can yet be given for the occurrence, as reported by Campbell *et al.* (1947), of four cases of disseminated sclerosis among seven workers engaged on research into swayback disease. A low copper content of their food could hardly be more than a predisposing factor, as in a highly developed country such as England the copper content of the diet cannot be supposed to vary much from one region to another, while the incidence of the disease among the general public is certainly much less than it was among these research workers.

Margulis, Soloviev, and Shubladze (1946) claim to have isolated a virus responsible for disseminated sclerosis; and perhaps, therefore, an infective factor is common to both diseases, a relative copper deficiency in the host being the predisposing factor. A possible explanation of the observation of Campbell *et al.* would then be that a copper content of the body sufficient to protect against chance infection was not sufficient to do so when the infection was massive. This of course is purely hypothetical; but it is not at variance with the known facts and does provide a hopeful basis for future work on the problem.

Suggested Form of Treatment for Disseminated Sclerosis

Whatever the precise relationship between the two diseases may be, the observation of Campbell *et al.*, supported by the facts recorded in this article, does strongly suggest that there is some relationship, and that it resides most probably in there being a common causative factor (or factors). It is therefore reasonable to suppose that a form of treatment effective against one disease will be effective against the other. Also, there is at present no form of treatment for disseminated sclerosis that is of proved value.

Thus, while mass prophylaxis against disseminated sclerosis by ensuring an adequate copper content of the diet is neither indicated nor practicable at the moment, there is in my opinion much to be said for treating established cases with copper sulphate. A daily dose of $\frac{1}{2}$ (16 mg.) is suggested. Even bigger doses than this have been found to be safe when given therapeutically over a period of many months to the four research workers who

contracted the disease. However, in view of the occurrence of enzootic icterus in sheep from copper poisoning, the possibility of overdosage with copper in man must be borne in mind.

Summary

Campbell *et al.* have recorded a striking incidence of disseminated sclerosis among workers engaged on research into swayback disease.

In South Africa disseminated sclerosis is very uncommon. So also is swayback disease; and except in those small areas where it occurs the copper content of the soil is high. Furthermore, treatment with copper is well known to be an effective means of preventing the disease and also of treating it.

It is therefore suggested that copper therapy of established cases be given a trial.

THE USE OF PROCAINE PENICILLIN IN CHILDREN

BY

J. L. EMERY, M.D., D.C.H.

Clinical Pathologist; Lecturer in Pathology, University of Sheffield

S. M. STEWART, B.Sc.

Bacteriologist, Demonstrator in Bacteriology, University of Sheffield

AND

D. G. H. STONE, M.B., M.R.C.P.

Resident Clinical Assistant to the Department of Child Health,

(From the Children's Hospital, Sheffield)

A penicillin preparation that will give a bacteriostatic blood level between infrequent injections has obvious advantages. There have been many attempts to increase the time interval between injections by suspending soluble penicillin in various media such as beeswax and peanut oil: these preparations have not been satisfactory.

Salivar *et al.* (1948) described the formation of an insoluble compound by the chemical combination of procaine and penicillin in equal molecular proportions. This substance dissociates gradually to liberate soluble penicillin, and when suspended in oil gives prolonged blood-serum penicillin levels in animals (Hobby *et al.*, 1948).

Several reports have been published on the use of an oil suspension of procaine penicillin in man. Since a single daily injection is aimed at, an analysis of the recorded 24-hour blood-serum penicillin levels has been made and is given in Table I. The only paper that is concerned with children is that of Carson *et al.* (1949). It will be seen that, in the larger adult series, 34 of 62 patients (Hewitt *et al.*, 1948), 33 of 78 patients (Thomas *et al.*, 1948), and 21 of 29 patients (Jones and Shooter, 1948) gave penicillin levels of over 0.03 unit per ml. 24 hours after the injection of procaine penicillin.

This communication reports an investigation at the Children's Hospital, Sheffield, of the serum penicillin levels

TABLE I—Summary of Published Work

Reference	Dose in Units	Type of Patient	No. of Patients	No. of Patients with 24-hr Serum Levels μ /ml.			Ratio of Cases Giving 24-hr. Levels of Over 0.03 μ /ml.
				<0.03	0.03–0.2	>0.2

	300,000	"	78				33 of 78

obtained in 50 children following the administration of procaine penicillin in arachis oil. Twenty-five were referred from the casualty department, and the remainder were cases in bed.

Method

The preparation of procaine penicillin in arachis oil is viscous, and accurate measurement is difficult. Accordingly empirical dosage on an age basis was adopted. The dosage was: 75,000 units (0.25 ml.) to children under the age of 18 months, 150,000 units (0.5 ml.) to children between 18 months and 5 years, and 300,000 units to older children. Eight of the youngest age group received 150,000 units. The injections were made into the vastus lateralis. The penicillin serum levels were estimated by the capillary-tube method described by Fleming (1943), using whole blood inoculated with Richard's strain of *Streptococcus pyogenes*. The blood used for assay was collected in Wright's capsules and was taken at varying times. In eight children the levels in the first few hours were followed to assess the rapidity of absorption. In all cases the serum levels were estimated at the end of 24 hours.

Results

In the eight cases which were observed during the first few hours after injection of procaine penicillin the penicillin serum levels rose rapidly, to reach a peak between two and six hours. Of a further eight cases in which the serum level was estimated 12 hours after injection, all had a concentration greater than 0.25 μ /ml.

An analysis of the 24-hour penicillin serum levels is presented in Table II. In 29 of the 50 patients the 24-hour

TABLE II—Analysis of the 24-hour Blood Penicillin Level on 50 Children Following Intramuscular Injection of Procaine Penicillin

Age	Dose Units of Penicillin	No. of Patients	Patients with 24-hr Levels over 0.03 μ /ml.
0–17 months	75,000	8	6
	150,000	8	7
18 months–4 years	150,000	16	9
5 years–15 years	300,000	18	7
In patients 18 months–15 years		19	11
Out-patients 18 months–15 years		15	5

levels were above 0.03 μ /ml. Of the 16 children under 18 months, six of the eight given 75,000 units and seven of the eight given 150,000 units had a 24-hour level over 0.03 μ /ml. Of the children over the age of 18 months, 16 of 34 had a level above 0.03 μ /ml. In this group 11 of 19 in-patients showed levels over 0.03 μ /ml. compared with five of 15 out-patients.

Thirty-six children received a further injection at 24 hours, and 26 of these showed an adequate concentration at 48 hours. Twenty-three were given a third injection at 48 hours, and 19 of these gave a level of over 0.03 u./ml. at 72 hours. The children presenting a low level after a second injection were not always those having a low level at 24 hours.

No patient showed a general reaction to the injection. In one child there was a localized swelling at the site of injection which resolved in two days.

Discussion

This study was confined to the investigation of serum penicillin levels, and no attempt was made to relate clinical change to the concentrations obtained. We have assumed that a minimum bacteriostatic serum level of 0.03 u./ml. is required. Although this level is that most generally accepted, the minimal penicillin level approved in some studies of procaine penicillin varies from 0.1 u./ml. (Carson *et al.*, 1949) to 0.01 u./ml. (Hewitt *et al.*, 1948); the direct comparison of results is therefore difficult.

The results that we have obtained are very similar to those reported in adults—i.e., that penicillin is present in the blood stream in significant amounts in approximately half of the cases 24 hours after an injection of procaine penicillin in arachis oil (see Table I).

A difference in 24-hour serum levels between ambulatory patients and in-patients was seen in our cases. These groups are small, but when considered with the cases described by Boger *et al.* (1948) they yield results which are just significant and indicate a more rapid absorption and excretion in ambulant cases. This point is important, as this preparation is most likely to be used in ambulant patients.

The results of Carson *et al.* (1949) differ a little from ours. The dose of penicillin that they gave to their children was approximately twice that given in the present series. Although they noted no exact correlation between serum penicillin titres and the amount of penicillin administered, the levels maintained at 24 hours were higher than ours, whereas the levels they obtained during the first six hours after injection were lower. This discrepancy may be due to the use of a penicillin preparation of a different particulate size.

By greatly increasing the dose of procaine penicillin it may be possible to attain a reliable 24-hour serum penicillin level. Higher doses have not been given in this series, because of the bulk of the injection, the possible toxic effects of absorbed procaine, and the inhibitory action on sulphonamides of procaine hydrolysed to para-amino benzoic acid (Carson *et al.*, 1949).

We conclude that procaine penicillin, owing to the variation of the 24-hour serum penicillin levels seen in this series and those of others, is not suitable for once-daily injection.

Preliminary trials with a procaine penicillin preparation containing aluminium stearate indicate that it may maintain more reliable blood levels.

Summary

The serum penicillin concentration after the intramuscular injection of procaine penicillin in arachis oil has been followed in 50 children.

Procaine penicillin was absorbed rapidly, but the penicillin titre in the blood after 24 hours was extremely variable.

Procaine penicillin in arachis oil is not an ideal preparation for the administration of penicillin by once-daily injection in children.

In-patients in this investigation were under the care of Professor R. S. Illingworth. We would also like to thank Dr. S. Doxiadis, of the Department of Child Health, and Professor E. J. Wayne, of the Department of Pharmacology, University of Sheffield, for the interest they have taken in this investigation.

ACUTE PORPHYRIA AND ASSOCIATED ELECTROLYTE CHANGES

BY

DEWI DAVIES, M.B., M.R.C.P.

The porphyrias are attracting increasing interest in Britain, though most of the work on the subject still appears in Scandinavian and American literature. The history of the porphyrias is reviewed by Nesbitt (1944).

Acute and latent porphyria are different phases of one disease, a chronic disorder of pyrrole metabolism which is sometimes familial. The aetiology remains unknown. Barbiturates, often cited as precipitating factors of the acute phase, seem to have been given following the onset of clinical manifestations in most cases. Symptoms usually appear between the ages of 20 and 45. The chemistry and reactions of the porphyrins have been reviewed by Dobriner and Rhoads (1940), Prunty (1946), Jørgensen and With (1947), and Discombe (1948).

The case of acute porphyria here presented showed most of the classical features of the disease. The presence of testicular atrophy, not previously reported, may be coincidental. Some cases may show only some of these features and urinary discoloration may be inconspicuous, so that only increasing awareness of the condition and of the test described by Discombe will lead to early and more frequent diagnosis.

Chronic porphyria and porphyrinuria, distinctly separate entities from acute porphyria, are respectively described by Mason, Courville, and Ziskind (1933) and by Rimington (1943).

Case History

A man aged 20 was admitted to a Royal Naval hospital on Nov. 14, 1947, with abdominal pain of four days' duration. His father had suffered from bouts of abdominal pain for several years and died at the age of 43 after a "cold" appendicectomy. His mother, two brothers, and a stepbrother by the same mother were well. Their urine showed no porphobilinogen or spectroscopic evidence of porphyrins. His alcohol consumption was negligible, and there was no evidence that he had taken drugs at any time.

He had been quite well until June, 1947, when he complained of periumbilical pain, vomiting, and constipation, and two days later (June 11) he was admitted to hospital. His symptoms continued for two weeks. The day after admission his pulse rate rose to 90-100. It remained so for three weeks and then fell to 85-90. The only findings were a mild anaemia

nd achlorhydria. He was symptom-free on discharge on July 25.

Apart from the loss of some 10 lb. (4.5 kg.) in weight he remained well until Nov. 11, when he was admitted on the fourth day of this illness. He complained of constant aching pain in the lower abdomen. He had vomited thrice and had obstinate constipation. The temperature was 97.4° F. (36.3° C.) and pulse 80. He looked thin and ill. The sclerotics had an unusual brownish tint, not due to bilirubinaemia. There was no pigmentation of the skin. He had generalized abdominal tenderness and considerable borborygmi. The testicles were small, measuring about 2 cm. in their long diameter. No other abnormality was noted. The temperature remained normal throughout the illness.

On the sixth day his pulse was 80. He was restless at night and was found sleep-walking. The next two days his pulse was 80-100 and the blood pressure 140/90. He was very miserable, lying curled up and complaining of his pain. All tendon-jerks were found to be sluggish. On the ninth day, after being delirious during the night, he had hallucinations. Acute porphyria was at this time first considered as a diagnosis on the combination of abdominal and nervous symptoms. The urine was macroscopically normal, but no chemical tests were done. The nightly administration of pentobarbitone ("nembutal") was stopped. On the 10th and 11th days his pulse was 90-120 and the blood pressure 115/85. Delirium and hallucinations continued, but pain had subsided. The urine on the 11th day had a pinkish tinge.

Examination with a Hartridge reversion spectroscope showed no definite absorption bands (but had a thick layer been used as recommended by Chandler, Harrison, and Rimington (1939) a positive result might have been obtained). The porphobilinogen test was not done. A psychiatrist diagnosed schizophrenia and advised transfer to a psychiatric hospital. This was done, but as it was still considered that the diagnosis was acute porphyria urine was kept for further examination. In three days this became dark brown in colour, and spectroscopy showed the absorption bands of acid porphyrin.

He was brought back to the general ward on the 16th day. He was mentally clear, and had noticed weakness of the arms, with difficulty in sitting up, for the previous two days. The urine appeared normal when passed. The pulse was 80-120 and the blood pressure 120/80. There was only flickering contraction of deltoid and pectoralis major muscles, with slight weakness of all the arm muscles. Biceps-jerks were absent. Flexion of the spine was very weak. On the 20th day the knee- and ankle-jerks were absent and there was some weakness of the legs.

Between the 22nd and 24th days he was again restless and delirious. Impaired pain sensation was found on the inside of the thighs. His condition was critical between the 24th and 28th days, and his pulse rate rose to 140. Thereafter there was very gradual improvement. By the 36th day he was mentally alert, there was some increase in power in arms and legs, the knee and ankle reflexes were normal, and no sensory changes were found. The pulse was still 110-135. By the 55th day the pulse was 85-100 and the blood pressure 115/80.

In the 10th week there was transient nausea and abdominal pain and a phase of hypotension; the blood pressure was 95/70. By the 17th week there was still considerable weakness of the deltoids, and the pulse rate ranged between 85 and 100. During the 21st week he had another attack of abdominal pain lasting about a week. Twenty-six weeks after the onset he was gaining weight and his arms were improving in strength.

Porphobilinogen and porphyrins were found in the urine throughout the period following diagnosis. Detailed examination of the porphyrins was not undertaken.

Subsequent History.—On July 3, 1948, he was admitted to hospital under the care of Dr. G. A. Emmerson with a recurrence of abdominal pain and severe insomnia. Hypertension and tachycardia were present and low serum sodium and chlorides were recorded. His abdominal pain gradually subsided, but the pulse rate rose to 110-130. On July 14 he complained of hoarseness. Phonation appeared to be weak, and there was weakness of extension of the right wrist. He died

suddenly and unexpectedly on the morning of July 16. No barbiturates had been administered.

Post-mortem examination showed pulmonary oedema and some bronchopneumonia and a flabby, thin myocardium. The testicles were not examined. Dr. F. T. G. Prunty reported on some of the tissues sent for examination. The lungs showed bronchopneumonia. There was some old and active tuberculosis in a tracheo-bronchial lymph gland. The liver showed early central necrosis in some lobules, and the liver cells contained brownish pigment granules not yet identified. The kidneys contained epithelial debris in some capsular spaces and there was capillary congestion. The convoluted tubules were the site of cloudy swelling, and in some places atrophy and pyknosis of nuclei had occurred. The adrenals were greatly hypertrophied, and the cells of the fascicula in places gave evidence of lipid depletion.

Investigations.—Body weight: 13th day, 104 lb. (47.2 kg.); 27th day, 91 lb. (41.3 kg.); 40th day, 88 lb. (39.9 kg.); 75th day, 89 lb. (40.4 kg.); 110th day, 92 lb. (41.7 kg.). Urinary creatinine: 5th to 7th weeks, 0.5-1.4 g. per 24 hours. Urinary creatine: 42nd day, nil. Wassermann reaction negative. Fourth week: Serum bilirubin less than 0.5 mg. per 100 ml.; cephalin flocculation and Takata-Ara reaction negative; alkaline phosphatase, 3.8 King-Armstrong units. Quick's intravenous hippuric acid test: (30th day) excretion, 0.78 g. hippuric acid (as sodium benzoate); (107th day) excretion, 0.97 g. hippuric acid. Serum proteins (42nd day). 7.6 g.—albumin 5.3 g., globulin 2.3 g. Glucose-tolerance test (35th day): fasting, 74 mg.; $\frac{1}{2}$ hour, 110 mg.; 1 hour, 158 mg.; $1\frac{1}{2}$ hours, 146 mg.; 2 hours, 128 mg. per 100 ml. White blood count, 7,900-14,000 per c.mm. Red blood cells:—9th day: red cells, 4,790,000; Hb, 12.6 g.; 17th day: red cells, 4,670,000; Hb, 12.7 g.; P.C.V., 46/100; M.C.V., 98.5 μ ; M.C.D., 7.4 μ . 42nd day: red cells, 5,130,000; Hb, 14 g.; P.C.V., 50/100. 79th day: red cells, 4,600,000; Hb, 12.6 g.; P.C.V., 46/100; M.C.V., 100 μ . Electrocardiograms showed left axis deviation and very low T waves in leads I and CR4.

Electrolyte and Renal Function Changes in Acute Porphyrin

The occurrence in acute porphyria of low serum sodium and chloride was described by Abrahams, Gavey, and MacLagan (1947) and Linder (1947). They also noted that despite low serum levels the urine still contained considerable quantities of chlorides. Both suggested that there was adrenal insufficiency.

In the present case low serum sodium and chloride levels were confirmed. The patient was placed on a special diet with a varied chloride intake. Desoxycortone acetate and adrenal cortical extract were given in addition for two periods. During the investigation there was no vomiting, diarrhoea, or excessive sweating. The urinary excretion of chloride was estimated daily and the serum levels were estimated at intervals (see Table). Sodium balance might have been of greater value, but chloride estimations taxed laboratory facilities considerably less.

It was found that the chloride output was directly proportional to the intake, and that cortical extract and desoxycortone acetate had no effect on this. During the first period of administration the patient's condition was deteriorating, and during the second period spontaneous improvement had already started. During both periods there was a rise in serum sodium, but this seemed to be part of a gradual rise that took place throughout the period of observation rather than an effect of drug administration. Chloride levels showed considerably less change throughout. Potassium had fallen before the administration of desoxycortone acetate, and the initial high level may have been produced by increased tissue breakdown, as there was a pronounced loss in weight at this time. Dehydration was not obvious clinically, and red-cell estimations suggested its presence about the 42nd day only. The alkali reserve was normal throughout. These findings indicate that

Table showing Chloride Estimations and Serum Levels

Day:	17	18	19	20	21	22	23	24	25	26	27	28	39	47	53	57	64	71	79	107

23rd to 27th days: 10 mg. of desoxycortone acetate were given by injection daily. 48th to 53rd days: 10 mg. of desoxycortone acetate plus 5 ml. cortin B.P.C. were given daily. A total of 500 mg. of pantothenic acid was given intramuscularly between the 57th and 70th days.

adrenal deficiency played no part in the production of the electrolyte picture. This is in harmony with the post-mortem findings, which suggested adrenal overactivity rather than underactivity.

Broch (1945), in a varied collection of conditions, found similar electrolyte changes without any appreciable response to salt therapy. He could find no harmful effect attributable to the electrolyte changes in themselves, and warned of the danger of giving intravenous saline, in the absence of dehydration, in an attempt to correct the electrolyte levels.

Oliguria and a moderately raised blood urea are very often found in acute porphyria and are usually attributed to circulatory disturbance. Albuminuria occurs in the minority and is usually slight. It was absent throughout in the present case. Water balance and serum-urea levels are shown in the Table.

The urea clearance test on the 58th day showed 60% of average normal function in the first hour and 62.5% in the second hour, on the 78th day 64% and 56%, and on the 107th day 58% and 51%. Thus in this case there was evidence of relatively persistent renal disorder. The findings suggest that attention should be directed to the kidneys for the explanation of the alteration in serum electrolytes. That the kidneys are responsible is perhaps further supported by the findings in a recently observed case, not yet fully investigated, in which only minor changes in serum electrolytes were found and renal function appeared to be normal.

Pantothenic Acid Deficiency and Porphyria

Liver and vitamin B have been recommended for acute porphyria, but little improvement attributable to their administration has been recorded.

Pantothenic-acid deficiency in animals results in failure to grow, porphyrin deposits on whiskers, gastro-intestinal symptoms, tachycardia, prostration, neurological changes, and coma, associated with low blood chloride and raised urea. Post mortem there is myelin degeneration of the nervous system, degeneration of the liver, adrenal cortical exhaustion, and renal tubular degeneration (Deane and McKibbin, 1946). No defect in sodium conservation is revealed (McQueeney, Ashburn, Daft, and Faulkner, 1947). In this state there is at least superficial resemblance to acute porphyria. Further, it was shown that pantothenic acid will reduce or abolish porphyrin excretion produced by drugs (Hoesch, 1947). Its effect in acute porphyria was not studied.

In the present case 500 mg. of pantothenic acid was given by intramuscular injection between the 57th and 70th days. There was no appreciable change in the rate of clinical

improvement or in the pulse and blood pressure. It was not practicable to assess the quantitative excretion of porphyrins, but the depth of colour produced in the porphobilinogen test, though of little value in assessing quantitative excretion, showed no appreciable variation. Between the 64th and 71st days the sodium level, previously steady, rose from 280 to 320 mg., and this level was maintained. There was a temporary rise in urea (see Table).

Thus the only evidence of a beneficial effect from pantothenic acid was given by the serum sodium level. Whether this was therapeutic or coincidental can be assessed only by its trial earlier in a crisis. That a deficiency of the vitamin is a factor in precipitating a crisis seems unlikely.

The conclusions arrived at are: (1) that the changes in serum electrolyte levels in acute porphyria are not dependent on adrenal cortical deficiency but are probably due to renal damage; (2) that pantothenic acid, reported as beneficial in chemically induced porphyrinuria, is of doubtful value in acute porphyria, though further trial is advisable. I realize that conclusions drawn from the investigation of a single case may require modification with further experience.

Summary

A classical case of acute porphyria is presented. The previous finding of low serum sodium and chloride is confirmed, and it is shown that these are not due to adrenal deficiency but are probably dependent on renal damage.

The relationship between pantothenic acid and porphyria is discussed and observations during pantothenic acid therapy are described.

I am indebted to the Medical Director-General of the Navy and to Surgeon Captain J. G. Holmes, Royal Navy, for permission to publish this case, and to Surgeon Commander H. J. Bennett, Dr. G. A. Emmerson, and Dr. F. T. G. Prunty for use of their findings. I wish to thank Dr. Philip Hamill and Dr. A. J. Shillitoe for advice and criticism in the preparation of this paper, and, above all, Sick-Berth Petty Officer J. G. Scott for his valuable laboratory work.

RETAINED PLACENTA AND POST-PARTUM HAEMORRHAGE

BY

H. L. SHEEHAN, M.D., D.Sc., F.R.C.P.

Professor of Pathology, University of Liverpool

Though the complications during the third stage of labour and immediately after it are really the province of the obstetrician, it may perhaps be of interest to consider them from the somewhat different point of view of the pathologist. The following observations are based on a series of 98 patients with such complications who died and were studied at necropsy at Glasgow Royal Maternity Hospital. Sixty-six of these patients died as a direct result of haemorrhage and shock, nearly always within 12 hours after the delivery of the baby. The other 32 had similar haemorrhage and shock but recovered temporarily; they died later in the puerperium from other causes.

It will of course be clear that the relative frequency of the complications of the third stage in the present series of fatal cases is probably not the same as that in patients who do not die. It should also be remarked that the present data cannot be compared directly with those of Glass and Rosenthal (1948), as the cases have been classified on quite different lines.

Retained Placenta

For the present analysis the placenta has been considered as "retained" if there was delay or difficulty in its delivery, and also if severe haemorrhage occurred early in the third stage and necessitated emergency measures for the removal of the placenta. The cases have been divided into five groups according to the main factors causing the retention. These factors were determined from the necropsy findings when all or part of the placenta remained in the uterus at the time of death, and from the obstetrician's description of the details of removal when the placenta had been removed during life.

Constriction Ring (2 Cases).—In this type the placenta separates completely but is held in the uterus by a constriction ring (Fig. 1). This is only a rare cause of death. Both patients had manual removal, but died a few hours later.

Atonic Non-detachment (45 Cases).—This failure of separation of a normally attached placenta is a common cause of death. If the placenta is still in the uterus at necropsy the uterus does not appear well retracted; the upper three-quarters of the placenta is attached as it had been during the pregnancy, but its lower portion (about one-quarter) is usually separated. The placenta is not pathologically adherent anywhere, and can be peeled off quite easily from the opened uterus (Fig. 2). When the placenta has been removed before death the uterus appears quite normal at necropsy and is well retracted; it does not contain placental remains, though if the patient has lived for a few hours after

the removal there is the usual small mass of clot attached to the placental site.

The haemorrhage that occurs in many of these cases is well accounted for by the separation of the lower edge of the placenta. The failure of separation of the whole placenta appears to be due to uterine atony during the third stage. The present series of cases give no clear information why this atony occurred. Throughout the second stage the uterus had functioned excellently; the labours were nearly always normal, though a few were unduly short, and only two of the patients had an anaesthetic for the delivery. During the third stage there is clear evidence of atony, and it might reasonably be expected that this atony would continue subsequently. However, as soon as the placenta is delivered the uterus appears to act normally; none of the patients in the present series had haemorrhage after the placenta was removed.

A study of the general data shows that a rather high proportion of the patients were advanced multiparae and that two of them had had a retained placenta at the last delivery: the evidence from the present series is insufficient to allow of valid conclusions on the significance of these factors.

Partial Adhesion (18 Cases).—This group of cases is characterized by an abnormality of attachment of the placenta at one part of the uterus, usually in its upper half. The placenta bulges out into a bay in the uterine wall so that the myometrium is thin, sometimes only 2-3 mm. The placenta can be removed from this site at necropsy only by tearing through the attachment, leaving small tags behind. The underlying myometrium is quite tough; in the present series the wall was never perforated in the course of manual removal during life or in tearing off the placenta at necropsy. Occasionally the whole placenta is found in the uterus at necropsy, but the commoner condition is that most of the placenta has been removed, leaving a mass adhering in its bay in the uterine wall (Fig. 3). If the placenta has been completely removed during life the only remaining evidence is the area of very thin uterine wall.

Complete Adhesion (6 Cases).—This is the condition known as placenta accreta. The adhesion is similar to that in the previous group, but is almost universal instead of being limited to only one or two areas. The uterine wall is scalloped out into a series of bays, each of which may be very extensive (Fig. 4). The adhesion is sometimes so complete that no separation occurs at all and there is thus no haemorrhage. Usually the patient dies with the placenta in the uterus, or she has a hysterectomy. However, in two of the present cases the condition happened to be met with in the course of a caesarean section, and the operator removed the placenta by blunt dissection.

The last two groups, the partial and the complete adhesions, appear pathologically to be merely different degrees of the same process. This seems to originate early in pregnancy, as it occurs in some abortions. It was associated with placenta praevia in eight of the present cases; the adhesion in these was commonly in both the upper and the lower segments. Previous retained placenta and previous puerperal

FIG 1.—Constriction ring

FIG 2.—Attached non-adherent placenta

FIG 3.—Partially adherent placenta

FIG 4.—Accrete placenta.

infections do not appear to be important factors, as adhesion occurs in primiparae with the same relative frequency as in multiparae. The condition has no obvious effect on uterine function: many of the labours were short, and the average duration of the first and second stages together was 15 hours.

Intraperitoneal Rupture (2 Cases).—These were ruptures of the uterus with escape of the placenta into the peritoneal cavity so that it could not be delivered.

Factors Leading to Death from Retained Placenta

Most of the patients die within eight hours after the birth of the baby; the particular manner of death appears to be a combination of shock and haemorrhage in varying proportions. There are three factors to be considered in this connexion: blood loss, traumatic shock due to the manner of removing the placenta, and the length of the third stage of labour.

Blood Loss

Some patients have brisk haemorrhage; others have a gradual but continued blood loss which may be much greater than is appreciated. These patients may die from haemorrhage unless treated early by adequate blood transfusion. But many patients have relatively little blood loss, and death in these cases seems to be due essentially to shock.

Trauma of Interference

Every obstetrician has seen patients who collapsed shortly after forcible expression of the placenta or after manual removal. This has led to the widespread condemnation of both these procedures: it is usually maintained that manipulations such as these are of their very nature almost bound to lead to shock. On the other hand, the trauma involved cannot be compared with that which occurs in the ordinary process of delivery of the baby, and this does not cause shock. The present series of cases happens to give some information on the problem of whether these methods of removing the placenta are in themselves productive of serious shock.

In the hospital where these necropsies were performed there were three obstetric units, each of about the same size and with the same intake of patients, so that their results may fairly be compared. The chief obstetrician of one of these units held very strong views on "mismanagement of the third stage." His guiding principle was to leave the placenta to separate naturally even if this took a long time. He made strict rules in his unit that there should be no interference with the uterus. Control of the fundus was allowed, sufficient to prevent bleeding, and gentle expression was permitted when the placenta was obviously lying free in the lower segment or vagina. Apart from this, there was a clearly stated policy against expression, Credé's manoeuvre, or manual removal. On the other hand, in the other two units the staff was allowed considerable freedom in attempts to get the placenta away. Expression of various types was attempted, probably in many cases with ascending grades of force, and, if this was unsuccessful, manual removal was performed. (Intravenous ergometrine had not become a recognized treatment at the time these cases occurred.) The Table shows the number of deaths in the three units.

Results of Treatment of Retained Placenta

	Interference Unit 1	Interference Unit 2	Non-interference Unit
Deaths within 12 hours:			
Placenta delivered ..	9	9	5
Placenta <i>in utero</i> ..	4	2	11
Deaths after 12 hours:			
Placenta delivered ..	6	12	7
Placenta <i>in utero</i> ..	0	0	4

The 16 early deaths in the unit where non-interference was the rule are not significantly different from the 13 or 11 early deaths in the other two units (which are termed, purely for contrast, "interference units"). The only obvious effect of the policy of non-interference was a tendency for the patients in that unit to die with the placenta still *in utero*. So far as these figures go, they suggest that, though forcible expression and manual removal may not be ideal procedures, their omission in cases of retained placenta is at any rate just as harmful to the patient as their performance. It does not appear that progress in the treatment of retained placenta will be achieved along this particular line of non-interference.

Duration of Third Stage

The most striking point in the present series of necropsies is that, with certain special exceptions which are discussed below, the third stage of labour had been allowed to continue for three hours or more. This is shown in Fig. 5

which deals only with the patients who died of haemorrhage or shock. The clear parts of the columns indicate the time of removal of the placenta; the patients lived, on the average, about two hours longer. The black parts of the columns

FIG. 5.—Duration of third stage of labour. Clear parts of column = time of removal of placenta; black parts = patients who died with placenta still *in utero*.

represent patients who died with the placenta still *in utero*.

The six deaths following immediate removal of the placenta form a special group—three cases of caesarean section in which the placenta was found to be grossly adherent, and three cases of enormous haemorrhage which necessitated immediate manual removal but which was followed by rapid death, purely from blood loss. There were no deaths of patients who had the placenta removed between a half and two hours after the delivery of the baby. Most of the deaths occurred in cases in which the placenta had been left *in utero* for three to seven hours. The particular kind of treatment, whether removal of the placenta or leaving it in the uterus, did not seem to be a significant factor at this stage.

A great variety of interpretations can be placed on the significance of this prolonged third stage, but they are all speculative. The important question is whether the mortality would be reduced if the third stage was always completed in less than one hour—by oxytocic drugs or by expression or by manual removal. Unfortunately this question cannot be answered, as there does not seem to be an adequately controlled investigation of the matter.

Post-partum Haemorrhage

In the series there were 25 cases of severe haemorrhage following delivery of the placenta: 16 of these patients died within seven hours after delivery; the other nine recovered temporarily but died later in the puerperium. These fall into two groups.

Rupture of Uterus (6 Cases).—In these patients the cause of the bleeding was found at necropsy to be rupture of the uterus or significant cervical tears; the amount of the haemorrhage varied.

Reviews

MYOTONIA

Myotonia. Thomsen's Disease (Myotonia Congenita), Paramyotonia and Dystrophia Myotonica. A Clinical and Heredo-genetic Investigation. By Eivind Thomsen. Translated from Dutch by Finn Brink Carlsen. (Pp. 251; 17 figures. £1.) London: Universitetsforlaget i Aarhus. London: H. K. Lewis 1948.

Myotonia is defined as a peculiar functional disturbance of the musculature characterized by an abnormal protracted contraction. It is accompanied by a typical electrical phenomenon whereby muscular contraction continues for seconds and then subsides gradually. Myotonia is a manifestation of the hereditary disorders congenita (Thomsen's disease), paramyotonia (Eulenburg), and dystrophia myotonica (myotonia atrophica). These, though admittedly rare, are among the most important neurological affections. Dr. Thomsen's monograph contributes to the literature of this subject, and the English-speaking reader a detailed account of the manifestations. The author was fortunate in his personal experience of these affections. The clinical features of dystrophia myotonica are drawn from 21 families with 874 living members, among whom there were 15 cases of the disease. In the case of Thomsen's disease, he surveyed five families, comprising 465 living members, 19 of whom were afflicted with the disorder. Dr. Thomsen's attention to the syndromes described by Debré and Semelaigne in which muscle myotonicoid features are associated with myotonia is particularly interesting when discussed in relation to his views on the identity of Thomsen's disease and myotonica. He discusses the arguments for and against the conclusion that the two are identical.

MACDONALD CRITCHLEY.

OBSTETRICS

Obstetrics. By O'Donel Browne, M.D., F.R.C.O.G. (2nd edition, 1948, 35s.) Bristol: John Wright.

In this book O'Donel Browne has set himself an extremely difficult task, attempting to cover the management and treatment of all obstetrical conditions, normal and abnormal, within the limit of 250 pages. Even when theoretical considerations are omitted as far as possible, the field is large and much of it must of necessity receive a thin and unsatisfactory covering. In a work of this size it is perhaps a better policy to deal adequately with a few common obstetrical problems. This book has, of course, many good features, and among these may be mentioned the clear and well-illustrated accounts of the technical details of obstetric manoeuvres. In many respects, however, it invites adverse comment, despite criticism being forestalled to some extent by the author's pointing out that the book presents unqualified personal opinions and that it should be read in conjunction with the more standard textbooks rather than in place of them if the reader is to obtain a proper perspective.

Twelve years have elapsed since the first edition was published, and this period has seen great changes in outlook and practice in midwifery. To bring the book thoroughly up to date would therefore have necessitated rewriting it almost completely. As it is, it gives the impression that the revision has been patchy, and the effect is a rather curious mixture of ancient and modern. To take two examples only: penicillin is used for puerperal sepsis but not for acute mastitis; the modern classification of pelvic shapes is included, but the treatment of thrombophlebitis is the same as practised twenty years ago, and there is no mention of anticoagulant drugs. The absence of any attempt to indicate the relative importance of different conditions is also noticeable.

It may be that the author has often deliberately described treatment which is not ideal, having in mind those of his readers who will be called to practise under circumstances far

from perfect in some of the remoter parts of Eire. Indeed, the book is primarily intended for Professor O'Donel Browne's own students and to supplement his personal instruction to them. It may serve this purpose well, but the general reader will find it less helpful.

T. N. A. JEFFCOATE.

ECLAMPSIA

Eclampsie et Eclampsisme. By Henri Vignes. (Pp. 220. 450 francs.) Paris: Masson et Cie. 1948.

By this new publication Henri Vignes has increased his already great reputation. He has compressed into some 200 pages most of what has been written or recorded about eclampsia. Indeed, one cannot recall any comparable work on the subject, and it is hoped that it will be translated into English. The book is a typical French publication, with little effort to produce a table of contents and with none of the precise classification usually provided by German writers. Its success depends essentially upon clarity of expression and the wide knowledge of the author. References are ingeniously incorporated in the text, with references to the important papers placed at the bottom of each page. No publication of importance seems to have escaped notice, and proper stress is placed upon work done in Great Britain, though (on page 70) F. J. Browne is referred to as "Browe." The author stresses no particular theories and no particular therapies. His attitude is one of an impartial judicious summing-up. The volume merits the highest praise.

WILFRED SHAW.

VITAMIN DEFICIENCY SYNDROME

A Neuro-Vascular Syndrome Related to Vitamin Deficiency. By Hendrik Smitskamp. (Pp. 114. No price given.) Amsterdam: Scheltema and Holkema's Boekhandel.

During the recent war a group of Dutch medical men made a study of the malnutritional syndromes which were met with among the inmates of a Japanese P.O.W. camp at Bandoeng, Java. This group included Dr. O. L. E. De Raadt, otoneurologist, Dr. J. Schwartz, ophthalmologist, the late Dr. Buitelaar, neurologist, who did not survive the hardships of war, Dr. Van der Hoeven, neurologist, and Dr. H. Smitskamp, general physician. One section of their observations has already been published and reviewed—an M.D. thesis (Leiden, 1947) entitled "Pellagra in the Oto-neurology and Rhino-laryngology," by De Raadt. This book is also an M.D. thesis, and the author discusses the condition commonly known as "burning feet."

In Part 1 successive chapters are on the clinical manifestations, the results obtained by means of capillaroscopy, laboratory findings, and therapy; in Part 2 on history, current literature, aetiology, pathogenesis, the differential diagnosis from erythromelalgia, acrodynia, and acroparaesthesia. In 1943 some 700 patients were seen at a clinic set up for malnutritional disease; from these 347 were selected and formed the subject for study. The observations made by Dr. Smitskamp do not differ materially from those made by our own medical men in other P.O.W. camps in the Far East, but they form a very interesting and detailed complementary contribution to the subject. He noted that optic neuropathy occurred in 42.8% of the cases of "burning feet," and in 27.8% of those with "otoneurological aberration." "Epithelial lesions" (cheilosis, scrotal dermatitis) were very common, but occurred also among those not suffering from the syndrome—31% and 25% respectively. He remarks on the close association of the syndrome with signs of hyporiboflavinosis to the exclusion of beriberi and pellagra.

This paper will interest those who are familiar with the literature of the deficiency syndromes.

HUGH S. STANNUS.

A POPULAR SIGNPOST

Anaesthetics and the Patient. By Gordon Ostlere, M.A., M.B., B.Chir., D.A. Sigma Introduction to Science 15. (Pp. 166. 7s. 6d.) London: Sigma Books. 1949.

This is one of the "Introductions to Science" series, and fills a real need in being addressed to that large section of the intelligent lay public which is repelled by the sentimentality

and inaccuracies of most of the "popular" works on anaesthesia but cannot follow the highly technical style of scientific textbooks. Dr. Ostlere sets out in lucid and sober fashion the present position of anaesthesia and should reassure many a nervous patient about to undergo an operation. The author has considered his public to be of the average intellectual status of a preclinical medical student, and he has succeeded admirably in presenting his subject accurately without the use of technical terms—a task which must have been difficult. All the latest advances of proved worth have been included, and the book should do much to impress upon the public the importance of being looked after by a highly trained specialist anaesthetist. The type is clear, and four plates on glossy paper are included in the middle of the book.

C. LANGTON HEWER

PRE- AND POST-OPERATIVE CARE

Preoperative and Postoperative Care of Surgical Patients By Hugh C. Ilgenfritz, A.B., M.D., F.A.C.S. Foreword by Urban Maes, M.D., D.Sc., F.A.C.S. (Pp. 898, 110 illustrations, \$10 or £2 12s 6d.) St. Louis: The C.V. Mosby Company. London: Henry Kimpton 1948

During the last twenty-five years the risk in undergoing a major surgical operation has been much reduced, an improvement due in large part to the preliminary study of the patient and his preparation and aftercare. This book deals with these subjects, and is divided into two parts. The first thirteen chapters describe matters from a general standpoint, and the later sections give information about the management of disease in various parts of the body. This makes the book convenient for reference on any particular occasion, but increases its size and leads to a certain amount of repetition. Having said this, one can only praise the manner in which the subject has been presented. The physiological basis for each particularly recommended procedure is clearly explained, which makes the book readable and acceptable. And should the reader need more detailed information there is a good list of references at the end of each chapter. Every house-surgeon will want this book. It is of little use to him in a reference library. But it is expensive.

C. A. PANNETT.

MEDICAL ANNUAL, 1948

The Medical Annual: A Yearbook of Treatment and Practitioner's Index 1948. Editors, Sir Henry Tidy, K.B.E., M.A., 1 D.F.R.C.P. and A. Rendle Short, M.D., B.S., B.Sc., F.R.C.S. Pp. 68, 117 illustrations. £1 5s; subscription price £1 2s. 6d.) Bristol: John Wright and Sons 1948

In its sixty-sixth year the *Medical Annual* maintains the high standard it has long established and the reviewer's task in selecting particular contributions for comment is not facilitated by the general excellence of the work. Professor Tytler's authoritative review of B.C.G. will be read with interest by all whose work brings them in contact with tuberculosis. Dr. Mackenna's article on the treatment of cutaneous tuberculosis with vitamin D., and Mr. Barrett's on the surgery of the heart and great vessels, are both topical and instructive. Professor Crew's report on social medicine reflects the growing appreciation of the importance of this branch of practice. The book closes with the customary indices of pharmaceutical preparations marketed, and of British and American books published, during the year. The book production is of the high order expected from John Wright, and the half-tone and colour plates deserve particular commendation.

The *Medical Annual* for 1948, as usual, faithfully mirrors the advances in medicine and surgery for the year.

R. BODLEY SCOTT.

The number of books on chiropody—until recently a rather neglected literary field—grows apace. The *Textbook of Chiropody*, by Mrs. Swanson (E. and S. Livingstone: 20s), represents the teaching of the Edinburgh School of Chiropody. The book covers the subject adequately, if briefly within its 200 pages, an outstanding feature being the excellence of the illustrations; the use of a high-grade paper has allowed of almost perfect reproduction of the many photographs and skiagraphs. The production is up to the usual high standard set by Messrs. Livingstone.

PREVENTION OF SEA-SICKNESS

A dramatic account of a large-scale experiment on sea-sickness has just been published by Drs. Gay and Carliner,¹ of Baltimore. The American soldiers who cross the Atlantic in army transports often suffer from the rough seas. The conditions, according to the authors, are very different from those on ordinary passenger vessels, in which sufferers remain in their cabins and receive attention from stewards and nurses. In the troopship *General Ballou* (13,000 tons), 12 hours out of New York on Nov. 27, 1948, "the corridors of compartments were congested by sick men so ill that they were unable to reach the latrines. The men who reached these areas were unable to return to their compartments and remained stretched out in a semiconscious condition on the floors until more seaworthy individuals managed to drag them to the sick bay or back to their hammocks. The latrines became temporarily indescribably repulsive. . . . On the previous trip of the *General Ballou* from Bremerhaven more than 100 intravenous injections of saline solution were required to relieve a number of dehydrated persons."

During the voyage which began on Nov. 27 a series of tests were carried out with a drug known as "dramamine"—a compound of theophylline (with chlorine substituted for one hydrogen) with the substance well known as the antihistamine agent "benadryl." As soon as the ship left harbour a group of 134 men in one compartment of the ship were given 100 mg. of the drug four times a day for two days; none of these developed nausea and vomiting in this time. They were then left without treatment for 18 hours, and 41 by that time became sick. Dramamine was given again, and 40 regained their normal well-being within one hour of the first dose. These men were compared with a group of 123 men in another compartment who were given a placebo. Of these, 35 were sea-sick within 12 hours of leaving harbour. At the end of two days the sick men were given dramamine and obtained complete relief within one hour of the first dose.

In addition to this experiment in prophylaxis another experiment was carried out in which men were treated after they became sick; they were in a third compartment of the ship. Out of 129 men 15 became sick after 12 hours at sea. These were given 100-mg. doses of dramamine every five hours, and all but one were completely relieved. The one was partially relieved. In a fourth compartment containing 99 men 33 reported sick in 12 hours. They were given a placebo, which cured 19 whose complaints had

been merely of nausea and dizziness. The placebo, however, did not relieve the remaining 14, who became steadily worse until they were given dramamine, when all were cured. Further evidence of the curative value was obtained by treating 195 men who became sick out of 881 in other compartments. Of these there were only eight who were not relieved by taking 100 mg. of the drug every five hours. The 187 men who were relieved were treated for two days, after which administration of the drug ceased; 44 of them then became sick again within 12 hours.

These experiments justify the conclusion that dramamine is a non-toxic drug which can be used to control sea-sickness. It is interesting to observe that it can be taken by mouth or be given per rectum. This route was used successfully in men brought to the sick bay in a semi-conscious state. The capsule was punctured at each end, inserted in the rectum, and 30 ml. of saline was injected. Some of the conditions of the experiment with dramamine interfered with the fairness of the test. Thus in the first test described every man in one compartment was given dramamine and every man in another compartment was given the placebo. It would clearly have been better to give the drug and the placebo to men in the same compartment. Some men are sick when they see others sick and not before. The arrangement adopted therefore favoured dramamine.

During the late war much experience was gained in this country in the testing of remedies for sea-sickness, and a modest report of that work was published by Holling, McArdle, and Trotter² in 1944. They made no statement more definite than that, of a number of drugs examined, hyoscine "appears to be the most generally useful." The principal question which therefore arises is whether the new substance dramamine is a better remedy than hyoscine. The war experience made it clear that reports of the excellence of any one drug when not compared with another were untrustworthy. Some observers were convinced from their experience that amphetamine was of great value for sea-sickness. When compared directly with hyoscine, Holling, McArdle, and Trotter found it to be of no value at all. A comparison is valid only when the two drugs are used at the same time in the same ship, each being given to a sufficiently large group of men. It is therefore impossible to say whether dramamine is superior to hyoscine or not, for experience since the war in sea and air transportation has fully confirmed the value of hyoscine, of which proprietary preparations are on the market.

Gay and Carliner refer to the work of Holling and his colleagues on hyoscine and say that "the side effects from hyoscine were such that they did not recommend repeated doses." There is no statement of this kind to be found in the paper, and the only reaction which was observed was dryness of the mouth, though a careful watch for side effects was kept. The usual dose of hyoscine was 0.6 mg. (of hyoscine hydrobromide), but even after 1.2 mg. it "had no obvious effect on physical performance, ability to shoot, or on near vision." Although dramamine was not found to cause any reactions it seems unlikely that a substance so closely related to benadryl taken in doses of 100 mg. every five hours will be found as free from unpleasant effects as hyoscine.

WHITTILING DOWN

The difficulty already experienced of getting acutely ill patients into hospital will be increased by the 10% reduction in hospital costs recently imposed by the Minister of Health. For example, the cut in the budget of St. Bartholomew's Hospital is as much as £300,000. The original gross estimate for the budget of the United Manchester Hospitals was £1,224,720; with allowance for the Spens recommendations and domestic wage increases the total bill comes to £1,292,904. This group of hospitals has now been ordered to impose a cut of about £200,000. As some 60% of the total gross estimates is accounted for by wages, all of which are laid down by law, it follows that a heavy cut has to be made in the rest of the hospital budget. It is worth observing that according to Dr. R. D. Vanderwarker,¹ Director of the Passavant Memorial Hospital in Chicago, the payroll in U.S.A. hospitals is estimated to account for 60% of total hospital costs. Speaking before a section of the American College of Surgeons Dr. Vanderwarker also predicted that hospital costs would continue to rise. It is of interest to note that for the United Manchester Hospitals the medical salaries amount to £182,000, nurses' salaries to £183,000, and all other salaries to £349,000, making a total of £714,000. To illustrate the position in different parts of the country we give details of the 1949-50 budget for some of the provincial teaching hospitals. Oxford, for example, suffers a cut of £170,000 on an estimated expenditure for maintenance of £960,000; Bristol a cut of £120,000 out of an estimate of £970,000; Birmingham a cut of £87,708 out of an estimate of £1,308,329. Leeds and Liverpool on the other hand are incurring no cut in their estimate for maintenance, but on capital expenditure the former is to undergo a cut of £2,000 out of £52,000, and the latter £180,000 out of £300,000. The Provincial Group of the Association of Teaching Hospitals is requesting the Ministry of Health to give it information about the basis on which the cuts have been made, ranging from nothing to 25%. A Ministry of Health official is reported as saying² that even with the £9,500,000 cut the hospitals are getting more than they did last year. In 1948-9, it is stated, they received £172,796,000, and for 1949-50 they will be receiving £177,531,000.

The arbitrary fashion in which these cuts have been made suggests that hospital finance has got out of hand and the Minister of Health has temporarily lost command of the situation. There is much to be said for the suggestion made by Sir Frederick Menzies that a survey of hospital costs should be made by such bodies as the King Edward's Hospital Fund for London and the Nuffield Provincial Hospitals Trust, organizations with great experience in this field. There has, of course, been an increase in the cost of hospital administration. It may be asked whether at a time when hospital building is almost out of the question it is necessary to have architects appointed to Regional Hospital Boards; they receive salaries appropriate to architects but their function in fact seems to be that of clerks of works. The expense of out-

patients' dispensing is heavy, in one group of hospitals amounting to £30,000 a year for patients who should be treated by their general practitioners. In an important eye hospital in London the annual bill for providing spectacles is £63,000, although the dispensing is done more economically than in the Supplementary Ophthalmic Service. It is difficult to see how this hospital can cut its expenditure without curtailing the work in the out-patients' department and closing some wards. In fact, real economy would be effected if it was possible for its work to increase.

The most serious outcome of all this is the threatened closure of hospital beds. The Manchester Regional Hospital Board, for instance, has decided that if the cuts in capital and maintenance estimates are put into effect there will be 2,019 fewer hospital beds available for the already long waiting-list of patients. St. Bartholomew's Hospital had planned to reopen 330 beds, but the heavy cut in its budget now makes it necessary to keep this block closed. According to reports in the Press, Regional Boards fear that some hospitals will also have to be closed. If blocks of wards were to be shut down the cost per occupied bed in the wards remaining open would increase and hospital economy would be in a still more parlous state. All this comes at a time when it has been estimated that nearly 60,000 hospital beds in the country are out of use principally because of the shortage of nurses.

The Minister of Health has said that the reduced expenditure must be met with the least possible detriment to the welfare of patients. But at first glance it is difficult to see how the hospitals in this country can save nearly £10,000,000 without curtailing the services they provide for the public. The present situation should give the country some measure of the monetary value of the voluntary unpaid services rendered by hospital staffs to the community before July 5, 1948. If the Treasury and the Ministry of Health now find themselves unable to meet the bill Mr. Bevan may find it necessary to start once more hospital flag-days. The whole matter calls for urgent examination by those with long experience in hospital administration; it is deplorable that the National Health Service should suffer such a severe setback within a year of its inception.

OCCUPATIONAL DISEASES

It is over forty years since the principle of compensation for industrial diseases was first accepted in this country when, with the passage in 1906 of the Workmen's Compensation Act, six diseases were listed as entitling a workman to compensation. A new step forward was made by the introduction last year of the National Insurance (Industrial Injuries) Act, 1946. This Act introduces a new principle of workmen's compensation, for it establishes a system of insurance with contributions from both employer and employee to a central fund; the workman no longer seeks compensation for his injury from his employer but claims special insurance benefit from the State.

¹ *Science Newsletter*, April 16, 1949, p. 254.
² *Daily Telegraph*, April 28, 1949.

¹ *Report of the Departmental Committee on Industrial Diseases*, 1946. London: H.M.S.O.

In March, 1947, the Minister of National Insurance set up a Departmental Committee¹ under the chairmanship of Judge E. T. Dale to review the policy of scheduling diseases under the old Workmen's Compensation Act and to give advice on the principles which should govern selection of diseases under the National Insurance (Industrial Injuries) Act. The report of this Committee has recently appeared and contains much of medical interest. Evidence was given by numerous bodies, including the Royal College of Physicians, the British Medical Association, and the Royal College of Nursing. The Committee rejected as outside its terms of reference the suggestion that benefit should be paid under this Act for every disease that can be shown to be due to employment (a scheme known as "blanket cover"). The report points out that the Committee was concerned with the selection of diseases, and that therefore the inclusion of all diseases was not contemplated. The Committee then considered the three tests recommended by the Samuel Committee of 1906, which have guided those charged with the addition of new diseases to the schedule since the 1906 Act became law, and it decided that these tests were no longer appropriate. In the new Act the word "disease" is defined as "any departure from health capable of identification by its signs and symptoms." This wide interpretation should make it no longer necessary to label as accidents conditions (for example, ill effects due to the use of vibratory tools) which medically are regarded as diseases, a practice which leads to confusion.

The Committee rightly welcomes the use of the term "occupational disease" to replace the older term "industrial disease," with its narrower application, and lays down the criterion for judging a disease to be a risk of the occupation. Here again the move to widen the interpretation of the Act is seen; the Committee recommends that a disease be considered for inclusion in the list of "prescribed" diseases if the occupation entails special exposure to risk, such risk being inherent in the conditions under which the occupation is carried out—subject always to the proviso that individual cases of the disease can be attributed to the occupation with reasonable certainty. Incidence of disease alone is not to be regarded as confirming the relationship of a disease to an occupation, for it is recognized that incidence in a potentially dangerous occupation may be within normal limits because special precautions have been taken to control the risk. The report makes only passing reference to the difficult question of "aggravation," but it was agreed that the Minister was not precluded from taking it into account.

The report gives the impression that a rigid interpretation of the terms of reference might have been used to exclude consideration of the two highly controversial issues "blanket cover" and aggravation. The Committee does not, however, interpret these terms of reference with the same rigidity in other directions; this adds to the value of the report, for a useful expression of opinion on "time limits" is given, and the recommendation made that a workman whose employment in the relevant occupation ceased at a date outside a specified period should not be automatically excluded from benefit. The old rule often entailed great hardship and injustice (for example, to patients with malignant occupational disease with a long

latent period). The Committee also suggests that the time limits within which it may be presumed that a worker has developed a prescribed disease should have "closer relation to the nature of the particular disease."

The report concludes by recommending that the Minister should set up a specialized standing committee to consider the advisability of adding to the prescribed list diseases specifically referred to it, to keep under review the schedule of prescribed diseases, and to make suggestions about subjects for research. It is gratifying to find this emphasis being placed on the duty of the Minister to help forward research. Most industrial disease is preventable, and, while everything must be done to care for those who suffer from these conditions, such work can only be regarded as palliative—prevention must be the constant aim, and this should not be hindered by shortage of men or of money.

TOO SOLID FLESH

It is perhaps not surprising that in the U.S.A. interest in obesity as a medical problem is more acute than in this country. Even before the days of rationing American achievement had outstripped British, for Daniel Lambert, of Leicester, who died in 1809 at a weight of 52 st. 11 lb (336 kg.), has long since yielded the palm to Miles Darden, of Tennessee, who weighed 72 st. 13 lb. (463 kg.). For all this, obesity remains to every physician a problem of more than academic interest: its aesthetic disadvantages need no elaboration, but its influence on longevity and on the degenerative diseases are perhaps less well appreciated. American insurance statistics¹ show that the increase in the observed over the expected death rate appears to be closely related to the degree of obesity, particularly above the age of 45 years. A man 90 lb. (41 kg.) overweight is twice as likely to die in the next year as one of normal weight. In addition to arthritis and other disorders of an overtaxed locomotor system, obesity predisposes to diabetes mellitus,² hypertension, arterial degeneration,³ pulmonary emphysema,⁴ and cirrhosis of the liver.⁵ Its control is therefore an essential part of the prevention of these important and common disorders.

Reduced to the simplest terms, obesity can be regarded as the consequence of the body's energy intake exceeding its energy output. When opportunity is unrestricted, energy intake is a function of appetite, and obesity will result when appetite is not geared to the body's metabolic needs. This is true of all forms of obesity, and von Noorden's division into exogenous and endogenous varieties must be discarded. This statement, however, like most simplifications, obscures the intricacies of the problem. The obese do not absorb or utilize nutrients more completely than the normal; their mechanical efficiency is less rather than greater. The only variables are calorie consumption, which ordinarily depends on appetite, and calorie expenditure. The second may be affected by the activity of the endocrine organs, but in most obese patients it is in no way abnormal. Appetite must be accepted as the determinant

¹⁰ *Psychosom. Med.*, 1940, 2, 141.

¹¹ Ludwig, A. O., *New Engl. J. Med.*, 1948, 232, 175.

Nevertheless, it is a matter of common observation that the liability to obesity may be familial, and is often combined with a tendency to deposit fat after a definite pattern. The forms taken by this regional lipophilia may be determined by the endocrine organs, and Graham,⁶ in robust Australian idiom which spurns the spurious refinement of terms derived from the Greek, recognizes the "super-droopers, the spare tires, the big pants, and the grand piano legs." Danforth's⁷ account of a strain of yellow mice in which obesity is inherited as a Mendelian dominant confirms the clinical view that heredity is important.

If a constitutional, and often inherited, predisposition is admitted, appetite must still outpace metabolic needs to provide the material. It has been urged that familial liability is no more than a habit of overeating acquired from parental example. Bauer⁸ is unable to accept this view, and holds that there is a constitutional abnormality of adipose tissue throughout the body—a generalized lipophilia—of which voracity is the expression. Hypothalamic lesions, the result of disease or injury in man or experimentally inflicted in animals, are often followed by obesity. Here again increased appetite is mainly responsible, though reduction of basal metabolism and of physical activity plays a minor part.

In conformity with the trend of medical thought, the excessive appetite of many obese persons has been regarded as psychogenic. Neurotic traits are said to be common,⁹ and Bruch¹⁰ claims that the mothers of fat children are emotionally starved women who overfeed their offspring to compensate for a repressed feeling of hostility. Others see overeating as a form of addiction, the more insidious and dangerous as it carries no social stigma. Eating, they claim, can assuage a sense of loss, depression, or deprivation,¹¹ and the frustrated victim finds peace in directing his aggressive propensities against the good things of the table.

Whatever view is taken of the cause of the excessive appetite which results in obesity, there is no debate about the basis of treatment. Restriction of calorie intake alone will reduce weight. The too, too solid flesh will melt only when its possessor submits to an unbending discipline and exerts a rigid control over his appetite. There is no easy way.

TREATMENT OF PYOCOCCAL DERMATOSES

Some of the most troublesome and depressing dermatoses to practitioner and patient are the chronic follicular and flexural seborrhoeic infections, such as sycosis barbae, external otitis, and retroauricular, axillary, and inguinal dermatitis. Any treatment holding out hope of success in these conditions is welcome and must be investigated. Chemotherapeutic and antibiotic remedies have proved disappointing, even when laboratory tests have shown the infecting organisms not to be resistant. There is also a risk of aggravation resulting from specific epidermal sensitization to the drugs employed. The halogen-substituted quinolines, as "quinolor" ointment, have been used for several years with some success in the treatment of sycosis barbae. Recently American dermatologists have reported favourably on "vioform," a related quinoline derivative containing iodine and chlorine (5-chloro-7-iodo-8-hydroxyquinoline). This substance has for long been used internally in the treatment of amoebiasis, and on the Continent it is prescribed as an antiseptic powder and paste for septic infections. Elsewhere in this issue Dr. I. Martin-Scott (p. 837) and Dr. J. Overton (p. 840) report promising results with an ointment or cream containing 3% vioform in the treatment of sycosis barbae and allied seborrhoeic infections. The response appears not to be due to the iodine as

such, for vioform can be applied to the skin of patients sensitive to iodine. The number of cases reported on is small, and the period of observation is too short to form any final conclusions, but in most of the patients the improvement was rapid. A few failed to make progress, and in some relapses occurred while under treatment, but the general response was clearly superior to that obtained from most other forms of local therapy. Application of vioform only rarely caused aggravation of symptoms or irritation: in general the treatment appears to have a soothing effect, which is desirable in treating sycosis or flexural dermatitis.

It is unlikely that the promise of these early trials will be maintained. Sycosis barbae, like most constitutional ills, has its fluctuations and is apt to improve temporarily with any new form of treatment. A psychogenic, endocrine, nutritional, or toxic influence plays a major part in the aetiology of most of these dermatoses, and the surface infection is secondary. The cure is not likely to be found among the local antiseptics, but any measure of relief is a comfort to those afflicted with such ills.

MORTON'S METATARSALGIA

In 1876 T. G. Morton¹ described a severe type of metatarsalgia in which the pain was felt in the region of the fourth metatarso-phalangeal joint. In 1940 the late L. O. Betts,² of Adelaide, reported nineteen cases of metatarsalgia in which he had exposed the plantar digital nerve to the cleft between the third and fourth toes: in each case he found and resected a fibrous swelling of the nerve proximal to its point of division. In 1898 Robert Jones and A. H. Tubby³ advocated resection of the fourth metatarsal head for this condition; they feared that nerve resection would leave a painful scar and disliked making an incision through the sole of the foot. In a recent review of this condition Nissen⁴ records that in 1935 the late Sir Harold Stiles, who suffered from severe metatarsalgia, had the nerves to the interdigital cleft between his third and fourth toes explored by Mr. N. H. Dott, who found fibrosis of the epineurium of the branch from the medial plantar nerve: resection gave complete relief. Of the twenty-seven cases investigated by Nissen twenty-one were women and six were men. The ages of the patients varied between 23 and 55. The pain was severe and confined to the third and fourth toes and that part of the sole distal to the necks of the third and fourth metatarsals. The most constant physical sign was pain on upward and backward pressure at the base of the third and fourth toes. Nissen treated these cases by resecting the plantar digital nerve as it approaches the interdigital cleft between the third and fourth toes—a short vertical incision being made through the sole directly over the nerve. Histological findings proved that the lesion was ischaemic in nature. The digital artery may degenerate to no more than a fibrous strand. Thickening of the epineurium accounts for the bulk of the swelling. Local resection gives complete relief from pain, and the plantar scar is not a source of trouble. Similar findings have been reported by McElvenny⁵ and by Winkler and his colleagues,⁶ who regard the lesion as traumatic. Nissen's investigations, however, show that the lesion is caused by local ischaemia. He prefers the name "plantar digital neuritis"; the condition, however, is undoubtedly that described by Morton over eighty years ago.

POSTURE AND THE CIRCULATION

Postural hypotension is an expression of an imperfect adjustment of the circulation to bipedal existence. The two conditions in which a falling blood pressure on standing is the predominant sign are fainting and the much rarer orthostatic hypotensions associated with chronic neurological and endocrine disease. In the second group there is a state of long-standing apparent sympathetic paresis. Stead and Ebert¹ concluded that there was an abnormal response to the normal pooling of blood, and that as vasoconstriction failed the blood pressure fell. In the case described by East and Brigden² neurological disease was not present, but anhidrosis and impotence were accompanying symptoms. As in similar cases, there was no change in pulse rate with change in posture or the administration of atropine. They suggested that a central lesion of the sympathetic nervous system, possibly in the hypothalamus, would explain the findings. Vega Diaz³ recently reported in this *Journal* a case in which juvenile orthostatic hypotension disappeared with the development of slight hyperthyroidism, only to reappear after treatment for the latter condition had been given; he ascribed both conditions to hypothalamic disturbance.

Nylin and Levander⁴ have studied the circulation in a case of hypotension with the aid of tagged erythrocytes. Their findings were inconclusive, for the delayed equilibration of tagged cells after a change of posture might be explained by the fall of blood pressure *per se* rather than by a redistribution of blood. These authors give to the two conditions already referred to the names sympathetico-tonic and asympathetico-tonic orthostatism. They place in an intermediate group the cases in which orthostatic hypotension, often with tachycardia, develops after sympathectomy. Currens⁵ has measured the blood pressure of 1,000 men and women lying and standing. His findings confirm that a diastolic hypertension is common on standing; this may be a self-perpetuating mechanism leading to established hypertension. Man spends a large part of his time standing up, and the maladies mentioned are some part of the price paid for his assumption of the upright position.

AUTONOMIC RESPONSES TO BLADDER DISTENSION

In their paper on the automatic action of the bladder in patients with gross injuries of the spinal cord Head and Riddoch⁶ noted that in low cervical lesions distension of the bladder caused profuse sweating of the face, neck, and arms. Guttman and Whitteridge⁷ have recently investigated the autonomic responses to bladder distension in a number of patients with severe injuries of the spinal cord, using cystometry, skin-temperature readings, and plethysmographic studies of fingers and toes, and at the same time recording the pulse, the blood pressure, subjective sensations of the patient, and the appearance of sweating and pilo-erection. The autonomic responses were found to be related to bladder pressure rather than bladder volume. The invariable response to distension in patients with cord injuries at any level was vasoconstriction in the toes. When the spinal lesion was at T.6 or lower, that is below the sympathetic outflow to the arms, there was vasodilatation of the blood vessels in the fingers, little if any change in

blood pressure, and sometimes sweating of the lower part of the trunk and the legs.

It was in lesions above T.6, particularly in low cervical injuries, that the responses to distension were most conspicuous: in three men with severe spinal cord injuries in the upper thoracic region distension of the bladder caused patchy flushing of the face, the lateral aspects of the neck, the shoulders, and the upper part of the chest, and profuse sweating over the same areas and the arms. The nasopharyngeal mucosa became engorged, making breathing difficult, the pulse became slow, with extrasystoles, and the blood pressure rose. In these patients the vasoconstriction in the fingers was intense, and the considerable rise of blood pressure was thought to be due to widespread vasoconstriction caused by the reflex activity of the isolated distal segments of the spinal cord. The slowing of the pulse rate was explained as a reflex response to the rising blood pressure through the carotid sinus and aortic nerves, but it was more difficult to account for the vasodilatation of the face and neck and the congestion of the nasal mucosa. The sympathetic supply to the face and neck emerged from the spinal cord distal to the lesions, and vasoconstriction similar to that in the fingers might have been expected. These autonomic responses were considered to be an "adaptive mechanism," but their physiological basis remains uncertain. They are of some importance in the management of patients with spinal injuries, for they warn the patient and his attendants that bladder distension should be relieved. As Guttman and Whitteridge say, "They represent alarm symptoms indicating abnormal activity of a viscus in the anaesthetic area below the level of the lesion."

THE KING'S DOCTORS HONOURED

Honours for seven of the doctors who attended the King during his recent illness were gazetted on May 3. Sir Maurice Cassidy, Sir Thomas Dunhill, and Sir Morton Smart now become Knights Grand Cross of the Royal Victorian Order. Sir John Weir, who also attended his Majesty, was awarded the Grand Cross, which is the highest rank in the Order, in 1939. Dr. Horace Evans and Professor Paterson Ross have been appointed K.C.V.O., and the M.V.O. (Fourth Class) has been conferred on Mr. C. J. Longland and Mr. A. J. Slessor. It will be recalled that his Majesty invested Professor Learmonth with the insignia of Knight Commander of the Royal Victorian Order some weeks ago, and later Dr. John Gillies was made a Commander of the Order. Promotions in and appointments to the Royal Victorian Order are for extraordinary, important, or personal services to the Sovereign or to the Royal Family. The medical profession will welcome the announcement of these honours and the recent news of a continuing improvement in the King's health.

Sir Edward Mellanby, F.R.S., Secretary of the Medical Research Council, will deliver a lecture to commemorate the bicentenary of the birth of Edward Jenner at the Royal College of Surgeons of England (Lincoln's Inn Fields, London, W.C.) on Tuesday, May 17, at 4 p.m. He will speak on "Jenner and His Impact on Medical Science."

⁷ *Lancet*, 1949, 1, 223.

The next session of the General Medical Council will open on Tuesday, May 24, at 2 p.m., when the President, Sir Herbert Lightfoot Eason, will take the chair and deliver an address.

HEALTH PROPAGANDA

A new and nation-wide scheme of health propaganda was introduced by the Central Council for Health Education on May 1 and put at the disposal of all local health authorities in England, Wales, and Northern Ireland. Dr. E. K. MACDONALD, chairman of the Council, explained at a recent press conference that under the Public Health Act, 1936, and the National Health Service Act the duty of providing health education was laid upon the local health authority, a grant being obtainable from the Ministry of Health for this purpose. The Council's function was to provide advice and assistance to the health authorities, and with this object in view it was arranging the free, extended, and indefinite loan to them of exhibition material. This was in the form of transportable stands on which would be superimposed posters concerned with a series of topics. The material for each of these topics would remain with the authority for two months, after which it would be returned to the Council, refurbished, and reissued to other authorities so that there would be four sets of topics running the whole time for the first eight months of the campaign. New topics would be dealt with as occasion required.

The four topics on which posters had already been prepared were diphtheria immunization, the services provided in Part III of the National Health Service Act, food and drink infections, and sleep. Material relating to other topics was being planned so that each local health authority would receive further exhibition material (in exchange) every two months. The stands were constructed of wood and metal, attractively designed, self-lit, portable, and easily erected and dismantled. Each stand would have boldly inscribed on its fascia the name of the authority to which it was issued. It was suggested by the Council that they should be erected in large shops, show-rooms of gas and electricity companies, schools, cinemas, and other places where people congregated. Such exhibitions should be reinforced by a local campaign, and suggestions for ensuring good publicity as well as literature suitable for the particular topic, lecture-slides, posters, and other material were being offered to the local health authorities. In addition, the Council was preparing a number of leaflets for the use of medical practitioners. It was often helpful for a doctor to be able to hand to a patient a leaflet explaining what he had been telling him.

Medical officers of health who would like more information about the present campaign and other aspects of the Council's work should write to Dr. Robert Sutherland, the Secretary, Tavistock House North, Tavistock Square, W.C.1.

RED CROSS SAFETY ZONES

[FROM OUR CORRESPONDENT IN GENEVA]

The Red Cross is seeking to enlarge the bounds of its responsibilities and privileges. Its guardianship has been primarily concerned with the wounded and sick on the field and with prisoners of war. Now a new convention is being constructed for the protection of civilians in wartime—a big undertaking when the totalitarian shape of modern war is considered. Apart from providing for the protection of sick persons, the aged and infirm, children, and maternity cases, the convention sets out the rights of aliens, refugees, internees, and people in occupied territories. The draft convention was worked out at the International Red Cross Conference at Stockholm last autumn in the course of ten days, and now at Geneva 250 delegates from 56 governments, with 30 observers, are scrutinizing the draft, together with the drafts of the older conventions. But law-making by international assemblies is an exasperating business. Apparently innocent phrases open up unsuspected difficulties, amendments go backwards and forwards between principal commissions and drafting committees and subcommittees, with the result that in ten days the commission which is studying this new convention has considered only 18 articles out of 140, and many of the points which it has discussed have been left undecided.

One question which has come forward is the protection of civil hospitals from attack. Another is the right of free passage

of consignments of medical and hospital stores intended for civilians in an enemy country; a third, the setting apart of safety zones in regions where fighting is taking place, so that wounded and sick, whether combatant or non-combatant, may be sheltered, and those responsible for the supervision and food supply of such zones protected; a fourth, the permission to medical personnel of all categories to carry out their duties, and, again, the removal from encircled or besieged areas of mothers and children, the sick, and the aged.

In the article which proposes the immunity of civil hospitals it is stated that such hospitals must be as far away as possible from military objectives. But what are military objectives? In total war may not factories and industrial undertakings come within that category, and is there to be no hospital within easy reach? The objection was raised by the British delegate that the requirement was impossible in a highly industrialized community. Another article states that civil hospitals and their stores and materials must not be requisitioned or diverted from their purpose. But may not a military commander, faced with a sudden need for medical or hospital provision, seek the transfer of civil hospital accommodation or equipment? Another article lays it down that civil hospitals as well as all vehicles used for the transport of the wounded or sick must carry the Red Cross emblem (or the Red Crescent or Red Lion and Sun, as the case may be), and all medical and other personnel engaged at hospitals shall wear the Red Cross armband. But, as the Canadian delegation pointed out, this seems to be unnecessary in countries which are not themselves the scene of conflict. During the last war Canada suffered no air raids and saw no land fighting, yet by this provision all its hospitals from the Atlantic to the Pacific and all their staff would have to be decorated with the Red Cross. This may not seem very onerous, but if the Red Cross is too widely and familiarly distributed it may tend to lose its value and privilege. These and like points have engaged the commissions in hours of discussion, and one can only hope that the result will be an instrument which, if necessity arises, will be strong and availing. Perhaps it should be added that the five delegates of Soviet Russia are taking a useful and co-operative part in the conference.

BACTERIOPHAGE AND ANTIBIOSIS

PROFESSOR GRATIA'S LECTURE

A special university lecture in pathology was given at the London School of Hygiene and Tropical Medicine on April 22 by Professor A. Gratia, of the University of Liège. Sir Alexander Fleming presided.

Professor Gratia said that the word "bacteriophage" was first used some 45 years ago. This was in 1903, when Vuillemin used the phrase "une acrasie bactériophage." Then in 1917 the late Professor d'Herelle coined anew the word "bacteriophage" as describing the transmissible agent responsible for the lysis of *Shiga bacilli*. Two years later, during an epidemic of dysentery, d'Herelle observed that the filtrate of stools of recovering patients, when added to a new broth culture of *Shiga bacilli*, would bring about its dissolution. If the dissolved culture was then filtered and added to a second fresh culture of *Shiga bacilli* the same dissolution occurred again and so on indefinitely through a series of repeated passages. In the course of these passages the activity of the agent of lysis so far from weakening, was enhanced. Moreover, d'Herelle succeeded in obtaining the dissolution of typhoid, paratyphoid and other bacilli by passages of the active filtrate of these different bacteria. As this filterable lytic agent was endowed with the power both of multiplication and of adaptation d'Herelle claimed that it was a virus of bacterial cells—the same virus for all bacteria—and called it "bacteriophage."

Two Aspects of One Phenomenon

The lecturer then described the opposition to the virus theory in the early 'twenties, which was reminiscent of the famous quarrel about spontaneous generation. About this time the lecturer by chance came upon a forgotten paper by Twort on an attempt to cultivate vaccinia virus. Twort had observed that colonies of micrococci isolated from crude vaccinia pulp underwent a curious form of degeneration, this being carried

on indefinitely from one vitreous colony to a normal colony. Struck by the similarity between Twort's observations and those made later by d'Herelle, Professor Gratia repeated Twort's observations, and then, transferring a vitreous colony of micrococci isolated from vaccinia pulp into a broth culture of *Staph. aureus*, he was able to duplicate all the typical features of d'Herelle's phenomenon. He obtained a true bacteriophage active on almost any strain of *Staph. aureus* but entirely inactive on any bacteria of the enteric group. Thus it appeared that Twort's and d'Herelle's observations were two different aspects of the same phenomenon, and, contrary to d'Herelle's claim, there was not one single bacteriophage for all bacteria but there were different bacteriophages for different groups.

Later work demonstrated that bacteriophages were specific entities, behaving like germs. Nevertheless there appeared to be something of fundamental importance in the fact that phages seemed to multiply only in the presence of living cells of sensitive bacteria. An attempt was made to find out whether a staphylococcus would work on dead cultures of a staphylococcus. The first attempt seemed successful: broth cultures of staphylococci killed by heat underwent lysis when a small amount of phage was added. But it soon became evident that the phage was not directly responsible for that clarification, and that the real cause was the presence of a few living staphylococci in the mixture.

Approach to Antibiosis

This work suggested that there might be organisms endowed with the power of dissolving large quantities of bacteria. The question was how to detect them. The lecturer described at some length work then undertaken which showed finally that active strains of streptothrix or actinomycetes, isolated on bacterial agar, could dissolve as much as 10 times their own weight of bacterial suspensions in plain water of most saprophytic or pathogenic micro-organisms. But while living suspensions of Gram-positive bacteria were as easily dissolved as dead suspensions, Gram-negative bacteria were only dissolved when previously killed. Lysis was strongly inhibited by serum and also by electrolytes. As heavy bacterial suspensions when dissolved by actinomycetes maintained strong antigenic activity and at the same time lost their toxicity, he used them successfully, under the name "mycolysat," for the treatment of staphylococcal infections and in cases of typhoid, paratyphoid, or dysentery, and for carriers.

Thus, starting from research on bacteriophage, the field of antibiotics was entered. Those first steps showed the way and gave rise to the appropriate techniques for later discoveries. Finally, in 1944, *Actinomyces griseus* was isolated by Schatz, Bugie, and Waksman, and produced streptomycin, and now other antibiotics such as chloromycetin were being investigated.

Actinomycetes were not the only organisms which in the early investigations were found growing on plates of agar: there were also moulds as well as micrococci of all kinds. It was at this time (January, 1925) that the lecturer and his colleagues observed a contaminated culture of *anthrax bacillus* completely dissolved by a green mould, some kind of penicillium. At this time also he isolated a strain of *Bact. coli* which he called "coli V," producing an active substance which was not a phage, properly speaking, but some antibiotic agent, and this he called the "V principle." It was diffusible through "cellophane," while phages were not; it was remarkably stable to heat, while phages were thermostable, and, again, it had no antigenic activity and was not transmissible in series. Even at that early date he had been impressed by certain similarities which led him to consider the relationship between the two phenomena of bacteriophage and antibiosis, and this relationship had been confirmed by further work.

Investigations with a number of collaborators had shown that the antagonism between strains of coliform organisms, for example, was less specific than was originally supposed. Hundreds of active strains had been isolated from diluted human and animal faeces. The antibiotic products of these different active strains were not all identical: the appearance of their inhibition zones, their diffusibility into agar or through cellophane, their resistance to heat, to digestive enzymes or bacterial proteases, and the specificity of the resistant colonies appearing in the zones of inhibition showed great variety. These observations suggested that there were several different active

principles, to which—the generic name "colicins" had been given. At least 17 different "colicins" had been recognized and studied, and as a result of further work some 60 new bacteriophages had been obtained and classified into groups.

The lecturer showed a table giving the results of extensive tests of resistant colonies—resistant to "colicins" on the one hand or to bacteriophages on the other. He had previously shown that resistant colonies of coliform organisms selected by his "V principle" remained sensitive to phage and that other colonies which were resistant to phage remained sensitive to the "V principle." An investigation was then undertaken of all the resistant variants in this mass of material, comprising at least 17 "colicins" and 60 bacteriophages. He found that all mutants resistant to certain colicins were also resistant to certain phages, and his conclusion was therefore that, while there was no complete identity between the phenomena of antibiosis and bacteriophage, there was evidence of common factors, confirming the intuition which he had had 20 years ago that there was a relationship between the two. He resisted the temptation to enter into philosophical speculation about the nature of this relationship, and ended his lecture with a quotation from Craigie:

"Most of us probably feel that what is known about these various subjects (bacteriophages, nucleoproteins, transformation of pneumococcal types, genes) represents, so to speak, isolated jigsaw-puzzle pieces belonging to the same picture. When the missing intervening pieces are found and assembled in place a map of new territory will be revealed."

REHABILITATION OF THE DEAF

AMERICAN VIEWS

A postgraduate lecture with a transatlantic flavour was delivered at the Institute of Laryngology and Otology in London on May 7 by Dr. S. Richard Silverman, director of the Central Institute of the Deaf, St. Louis, Missouri.

Dr. Silverman began with the remark that, "with all due respect to my otological friends, the fenestrators, the irradiators, and the puffers and squirters," there was very little, medically and surgically, that could be done for the deaf; yet the otologist had great opportunities in dealing with the problem of the deafened. In the United States many factors had caused a recent surge of interest in this subject. Among them were the rapid developments in the science of electro-acoustics; the evolution of different surgical techniques, particularly the fenestration operation; new investigations into the physiology of hearing—despite the glib expositions in the textbooks. It was not yet known how the ear worked or how sound was converted into a nervous impulse; the popularity of motion pictures and the radio; and, finally, the tendency for "peripheral workers" (meaning politicians, social workers, and psychologists) to come together to do something for war casualties.

Hearing-aids

The greatest help offered to the deafened person was the vacuum-tube hearing-aid. There were two types of deafened persons: one requiring amplified sound, and hearing better when the voice was raised, the other able to hear speech of ordinary loudness but not able properly to distinguish syllables. With this second type, mere amplification only intensified the babel. The majority of persons who had purchased hearing-aids and discarded them belonged to this second group. On the other hand, certain people even in this category could be helped by a hearing-aid.

He had been quoted as saying that audiometers should be thrown out of the window, but that was a misinterpretation. The audiometer was a valuable instrument, but its limitations must be remembered. It could help in deciding in a given case whether a hearing-aid would be useful and to which ear it should be fitted. Broadly speaking, if a person had a loss across the speech-range of 30 to 35 decibels or more in the better ear the use of a hearing-aid should be considered. Putting aside cosmetic considerations, statistics would show that about 90% of patients needed air conduction instruments and 10% bone conduction.

No hearing-aid was perfect, and no hearing-aid could enable a person to hear as though he had normal hearing. Auditory training for the user of a hearing-aid must be insisted on not merely in manipulating the instrument but in obtaining what the lecturer called "cerebral reorientation" to speech. The user of a hearing-aid must learn to listen. Three levels of hearing might be defined: the primitive level, at which the person knew there were sounds but was unable to differentiate them; the awareness level, exemplified in the person about to cross the street; and the highest level, as shown in the exchange of speech. One of the most common expressions among deaf ex-Servicemen was that the world had gone dead; there was an eeriness in not hearing the traffic in the streets or the wind in the trees, and even at the primitive level to get some kind of sound appreciation was helpful.

Lip-reading

Dr. Silverman believed in the value of lip-reading, or "speech reading" as it was called in America. There was not much correlation between native intelligence and ability to lip-read. Many intellectual people—people in the professions—were poor lip-readers. Dr. Silverman tried an experiment on his highly educated audience. He wrote on the board the words "bat," "man," and "pan," then moved his lips without sound, and asked his audience which word he had pronounced. Opinion was about equally divided between the three words, and then he explained that they were all right and all wrong, because in the movement of the lips there could be no distinction between the three. Lip-reading was of value because it evoked some effort from the patient. Too often people supposed that treatment was something which was to be done to them. But rehabilitation, with hearing as with other things, was not effective unless the patient got hold of the idea that he was doing something for himself.

In addition to hearing-aids, auditory training, and lip-reading, one other thing was essential—namely, speech conservation or correction. The ears were the governors of speech. With impaired hearing speech began to deteriorate. He regretted to find in England speech correction so far divorced from the organization for helping the deaf. Finally, if hearing could not be improved or corrected, at least the patient might be taught to live with his disability graciously. Otologists and others often became so engrossed with decibels and frequency responses and articulation tests that they forgot that the patients themselves were not particularly interested in these things. The adjustment of the social and emotional life to the hearing defect was the important thing. The otologist should remember that a person who was hard of hearing was a person with a defective ear—not an ear with a person attached to it.

VISIT OF SWEDISH PAEDIATRICIANS

Last week the British Paediatric Association entertained as their guests some 30 distinguished paediatricians from Sweden. The British Medical Association held a reception on May 2, and later in the week Swedish paediatricians joined the B.P.A. in its annual meeting at Windermere. Many British doctors had the opportunity of meeting our Swedish guests at a dinner held in their honour on May 3 in the Apothecaries Hall, London. Dr. Hugh Ashby, President of the B.P.A., in a speech of welcome said that this was the first time his association had invited a group of paediatricians from another country to attend its meetings. This event happily coincided with the 21st anniversary of the founding of the B.P.A. Great advances had been made in paediatrics in Sweden during recent years and had been followed with intense interest by workers in Britain. At the same time he thought that the fall in infant mortality in this country from 150 to 34 per thousand in 50 years was "pretty good going." New Zealand was the only other country with which the record of Sweden for small infant mortality could be compared. Sweden had perhaps the most modern children's hospital in the world. Medicine, concluded Dr. Ashby, should become more international, and this would be helped by such visits as the present one and the delightful visit paid by the British Paediatric Association to Sweden last year, where they had been so hospitably treated.

In reply Professor Lichtenstein said that during the seventeenth and early part of the eighteenth centuries Swedish doctors were in the habit of visiting the country of Sydenham and Glisson. He mentioned the Swedish indebtedness to British workers, observing that international co-operation was more necessary now than ever before. He ended by saying, "We know in Sweden that if we enjoy freedom of thought and speech and science we owe that to Britain."

Professor E. C. Dodds, Master of the Apothecaries, paid his tribute to Swedish science and said that in no country in Europe did they owe so much in the matter of collaboration. Professor Dodds made some interesting remarks on the history of the Society of Apothecaries. Lord Moran also spoke, and Lord Webb-Johnson praised the Manchester School of Paediatrics, saying that he had sat at the feet of Dr. Ashby's father, the author with G. A. Wright of that well-known work *Diseases of Children*.

Reports of Societies

PROBLEMS OF CHILDHOOD

The problems of young children engaged the attention of the Section of Paediatrics of the Royal Society of Medicine on April 22, Dr. JAMES SMELLIE presiding, and of the Child Psychiatry Section of the Royal Medico-Psychological Association on April 23, when Dr. MABERLY was in the chair.

Toilet Training

The Paediatrics Section first heard Mr. ADAM CURLE, of the Institute of Human Relations, give an account of the methods of training in primitive societies. In the more aggressive communities the belief in the necessity for cleanliness was enforced by threats and punishment, while in peaceful communities there was a more easy-going attitude, the child being allowed to acquire good habits in its own time. In the more sophisticated communities in the last 60 to 80 years better amenities in home life had heightened the impulse towards toilet training at an early age, using methods varying from threats of punishment or ostracism to rewards for success. Mr. Curle described some studies he had made of communities in isolated villages where everyone showed great interest in all the children. Some of the practices of the primitive societies, such as elaborate initiation ceremonies into adult life, gave the members a strong feeling of unity with the group in contrast to the practice in a more highly civilized society of surrounding a child with protective care and then leaving it to its own devices at adolescence, which produced a feeling of isolation.

Miss AGATHA BOWLEY, of the Foundling Hospital Research Centre, said that habit training was a misnomer; it was not a mere matter of conditioning, the emotions were involved. She quoted opinions of workers in this field that the child who was allowed to develop without training would, if provided with the appropriate utensils, train himself after the age of 18 months. It was possible to condition small babies to be clean, but with intellectual development the habit broke down and this caused distress to the mother and might damage the mother-child relationship. "Placid but not premature potting" was her advice, and the pot should not be too much in evidence until the baby was a year old and had formed a steady emotional relationship with one adult. Approval and disapproval should be only mildly expressed.

The discussion that followed showed a cleavage of opinion. Dr. R. S. MACKERRH pointed out that if no training was undertaken for the first 18 months there was an enormous amount of washing to be done. Dr. I. HELMAN spoke of the results of a survey she carried out to discover whether the attitude of "saving the washing" was justified. She found that few children were clean before the age of 2, regardless of when training was begun. This was important, because a great deal of energy was wasted by too early a start, and the happy relationship between mother and child might be jeopardized. With children whose training started nearer the age of 2 the training seldom took more than a few months.

Dr. LINDSAY BATTEN said that as soon as a child got on to a mixed diet its urine became more irritating, and it was extremely

common for children of over eight months to have very sore genitalia. If they could be persuaded to be wet less often it would be an advantage. Dr. PATRICIA HOLMAN said that it was not good enough to say that the mother should put up with the washing, especially in a working-class home. That might be the last straw which destroyed her health.

Dr. LETITIA FAIRFIELD reminded the meeting that life was not only for babies; adults were entitled to some consideration. It was doubtful whether a child would correct itself automatically; some gentle pressure and direction from adults were needed. Dr. FELIX BROWN said that children should achieve habit training sooner or later, but excessive pressure should not be put upon them. Dr. SMELLIE said that there was such a thing as the gastro-colic reflex, and normal physiological functions could be encouraged, promoted, and trained.

Psychiatric Aspects of Infant Feeding

At the meeting of the Child Psychiatry Section of the Royal Medico-Psychological Association, Dr. RICHARD H. DOBBS said that after birth the most important happening in the child's life was feeding. The mother had comparatively simple instincts, but superimposed on them there might be emotional difficulties; she might have fears that she would fail, or she might have feelings of prudery and disgust which would complicate the process of breast-feeding. Breast-feeding was of great importance for the future character of the child. Breast-fed children suffered much less from ailments and had a lower mortality rate than bottle-fed babies, but the disadvantages of bottle-feeding disappeared as poverty was left behind and there might come a time when it would be difficult to point to a better survival rate as one of the advantages of breast-feeding. Regular feeds were not essential nutritionally or medically, but a certain routine and habit in feeding was a good thing if it could be achieved without any great disturbance either to lactation or to the child's comfort. Motherless babies did not miss their mothers for the first six or seven months, but in later years they might suffer harm if there was a constant stream of nurses; even if there was only one she would not provide the extra love and care which a mother bestowed, and this was of importance in later years.

Dr. MILDRED E. CREAK said that the hurried impersonal routine carried out in many maternity units where the baby was kept in the nursery and given to the mother only at feeding times had created many difficult situations. The baby should be kept near its mother. Dr. MABERLY said that it was desirable that the child-guidance clinics and the maternity and child-welfare centres should work closely together.

Children in Hospital

Dr. A. G. WATKINS, Royal Infirmary, Cardiff, said that every child should be seen first in the privacy of a small room by a responsible medical officer and an experienced sister. The child who caused trouble in the ward was usually the child who was already maladjusted. Normal children settled down quickly, and the grossly defective child did not give much trouble, but the mildly defective child was sometimes difficult. A great deal depended on how the parents had approached the child regarding its need for hospital treatment. The acutely ill child adjusted quickly to the new surroundings and appreciated the comfort provided. The child should be allowed to bring its own toys, especially the ones it usually took to bed. If a child was old enough, any procedure to be carried out should be explained beforehand. A full explanation should also be given to the parents by the doctor; they were more satisfied and then the child was more contented. Certain types of children were upset after visits; others were better after a visit from the parents. This was something one could not be too dogmatic about. It should be left in the hands of the sister to decide whether a child should be allowed visitors or not. He never hesitated to allow visitors when a child was desperately ill.

Miss ANNA FREUD said that when a child was ill it was easy to forget how harmful it was for the child to be in a state of anxiety, separated from its home surroundings. Those who worked in hospitals said that children were better behaved, they resented less what was done to them, they were less easily

emotionally upset, and they usually ate and slept better, but this was because the child became all body and its individuality retreated. Mind and body worked together and it was not profitable to treat them separately. There was a great deal of evidence that in the child, whether ill or well, the life of the body was accompanied by a rich life of the mind. Young children separated forcibly and for a long period from their mothers showed all the signs of a melancholic state, including even the signs of arrested bodily development. The child was not only separated from familiar people, he was separated from all his habits, and this might create as grave a disturbance.

Children of school age put much of their feeling into their interests; in hospital their interests had to be left at home, and such occupation as they had would not take up more than a few hours in the day. Children of that age needed continuous occupation. When a child was ill it lost interest and had the experience of being nursed again. Some children reacted by sinking back into babyhood or else they reacted against nursing care. Many children regarded the pain they suffered and the restrictions imposed upon them as punishment, and to such children the experience of being ill was dangerous. When children went through an illness at home they were helped by the people who knew them. In hospital they went through a difficult experience in isolation.

Dr. MABERLY felt that nurses preferred the depressed melancholic child because it was easier to manage. He mentioned the possibility of the mother coming into hospital and taking part in the nursing of the child, which seemed to be a successful solution to one part of the problem. Dr. HUNTER, of the Tavistock Clinic, said that children were much less keen on seeing their parents after six or eight weeks in hospital. The problem of the child who had to be nursed in a cot was interesting; such children appeared to suffer from a particular form of withdrawal not experienced by children who were up and about.

CARE OF THE ELDERLY

The Medical Society for the Care of the Elderly held a conference at Liverpool on April 1 and 2, in Belmont Road Hospital. The meeting was opened by Sir HENRY COHEN, who paid tribute to the work of Dr. Lloyd Hughes, the regional medical officer for Liverpool, and praised the work which had been done at Belmont Road Hospital.

Dr. LLOYD HUGHES described the steps which were being taken to meet the problems of old age in the region. He mentioned the setting up of a geriatric advisory committee to start work on these matters and outlined the progress which had already been made. Dr. Lloyd Hughes stressed the importance of finding housing and accommodation for those elderly patients who could be discharged from hospital. The Nuffield Foundation were contemplating the creation of experimental "half-way houses" for such cases in Liverpool.

Lord AMULREE told the conference of the interest which the Ministry of Health was taking in the prevention and treatment of sickness in the elderly. It was important for those who were doing the work to make their needs and their plans for future development known to the hospital management committees and regional boards. The Ministry would lend a sympathetic ear to any suggestions likely to free beds badly needed for other patients.

Dr. C. O. STALLYBRASS spoke on the work of the geriatric advisory committee. The members had made it their duty to look into matters personally and had tried to formulate some general principles. They had found that with old people social and psychological problems were as important as the purely physical ones. When all these had been investigated and assessed, treatment of the old person could begin.

Dr. D. G. HENRY, who had been medical officer to the Belmont Road Hospital for eighteen years, spoke as a general practitioner. More old people had to be cared for by fewer young ones. At the same time, the sense of responsibility within the family had altered. Besides the temperamental difficulties arising in the aged, current social conditions sometimes led to malnutrition. Extended social welfare activity was needed.

Miss CAPLE, almoner to the Leeds Geriatric Unit, also emphasized this aspect, while Dr. R. N. TATTERSALL gave an account of the medical work in this unit. He stressed the need for preliminary investigation and assessment of all elderly patients coming into hospital, mentioning the wide variety of pathological conditions encountered.

Inactivity in Old Age

On the second day Dr. J. W. AFFLECK, of Leeds, read a paper on "Personality Factors in the Senile Psychoses." The patient must be regarded as a personality and not just as a case of senile dementia or paranoia. The various types were intermingled in the elderly and were modified by the social surroundings of the old person. Dependence on others, loneliness, and physical disability complicated the picture and gave the patient little opportunity to regain lost self-esteem.

Dr. MARJORY WARREN reviewed the results of inactivity in old age. After describing some aspects of physiological deterioration she mentioned the psychological apathy associated with prolonged rest in bed. Active treatment of all physical disabilities which limited a patient's mobility was necessary. All social and domestic agencies which could lighten the mental or bodily burden must be recruited, and team work was needed to tackle the life problem of the patient in a happy, congenial, and stimulating atmosphere. Whenever possible old folk should be kept at home and not sent to hospital.

Psychological difficulties were mentioned by Dr. R. KEMP. Hitherto the medical profession had turned away from the care of old people, and this neglect had led to many false ideas about disease in the aged. The troubles of the elderly were often more mental than physical. If bedfastness and demoralization were prevented, active treatment would often produce a surprising change in the patient's activity, health, and happiness.

Dr. T. H. HOWELL urged the need for more out-patient clinics for elderly patients. These, especially when combined with domiciliary visits, diminished the numbers of patients needing to enter hospital. He agreed with Dr. Kemp and Dr. Warren on the need to keep old people active and alert in their own homes.

After a discussion on chronic bronchitis by Dr. R. M. EVANS, a paper on malnutrition in the elderly was read by Dr. H. FULD. He compared his experiences at Belsen camp with some of the cases seen in Liverpool. Discussing the physiology of nutrition in old age, he criticized recent experimental work on diet in rats when applied to human beings. A low protein intake was often found in patients admitted to Belmont Road Hospital with tissue wastage, anaemia, and oedema. Avitaminoses were not uncommon, especially among the many old people who appeared to live on bread-and-jam and tea.

ALCOHOLISM AS A NEUROTIC SYMPTOM

Dr. R. D. NEWTON, speaking at the annual general meeting of the Society for the Study of Addiction held on April 19, said that there was still little agreement on the causes of addiction and little progress had been made in prevention or treatment. A primary difficulty seemed to be that alcoholism was sometimes regarded as a disease in itself, while at other times it was viewed as a symptom. Alcoholism or drug-taking might be included among other reactions in a psychopathic personality or might be symptoms of a neurosis or psychosis.

Addiction to alcohol was a behaviour disorder closely related to other behaviour disorders of hysterical origin. In investigating cases of addiction one would expect to find a history of hysterical personality. Children who were over-indulged or who had been starved of affection and fearful of punishment might have a character structure in which the sense of personal helplessness was so deeply embedded that it lasted throughout life. Their reaction to difficulties was to retreat within themselves and build up a world of illusion, and alcohol helped them to do this. Patients who alternated between self-pity and an aggressive anxiety which made it difficult for them to establish contact with their fellows took alcohol to blunt their sensitivities—a significant difference in the use of alcohol.

Dr. Newton gave some case histories showing addicts to alcohol as normal people in abnormal circumstances. No evidence was found of any constitutional or hereditary factors, and all the information available suggested that these patients could have been successfully treated for their psychological disorders in childhood, adolescence, or early adult life.

Mr. STANLEY LEE, F.R.C.S., secretary of the Society, in presenting the annual report, said that Professor Golla of the Burden Neurological Institute had accepted the office of president for the ensuing year. Money had been made available for research into the causes of the craving for alcohol. To carry on the Society's work it had been necessary to dip deeply into its reserves, and an appeal was made for new members and increased support.

HEBERDEN SOCIETY

The Heberden Society held a "Case Conference" on April 8 at the West London Hospital. This was an endeavour to approach the problem of rheumatic disease from a clinico-social aspect, and the technique used was that developed by the School of Social Medicine at Oxford. Dr. ALICE STEWART, from this department, took the chair at the invitation of the president of the Society, Dr. W. S. C. COPEMAN. Dr. Copeman, in opening the meeting, drew attention to the effect of the concentration by the teaching hospitals on the pathology of disease and on good teaching material to the neglect of the social implications of illness.

Two cases, one of rheumatoid arthritis and one of ankylosing spondylitis, were presented by Dr. R. M. MASON, and the social case work carried out was described by Miss M. W. EDMINSON, head almoner of the Arthur Stanley Institute, Middlesex Hospital, and Miss B. E. LEMAN, out-patient almoner of the West London Hospital. Dr. Alice Stewart questioned whether such cases would have occurred at all if social research work had been carried out as actively as had pathological. She thought that an epidemiological study of the rheumatic diseases in the community would be a valuable advance in the investigation of these conditions. She suggested that a committee of interested doctors and almoners should be set up to work out the main headings to be used in social case reports. These should include the family constitution, an assessment of major financial stresses, housing arrangements, relevant public services available, and follow-up arrangements. Finally, the results achieved by the various social services available, as distinct from the purely medical aspect, should be assessed at some time in each individual case.

Preparations and Appliances

SET OF NESTED RETRACTORS

Sir HENEAGE OGILVIE writes: In my Bradshaw lecture in 1947 I described a set of nested retractors. The ones I was then using were a home-made set made before the war by my chauffeur. Since the lecture I have been working out the design with Dr. Greville, of the Medical Supply Association, and have, I think, got a satisfactory pattern as is possible within the limits of compactness. I and my colleagues at Guy's Hospital find these retractors very useful for all operations at the bottom of a deep cavity, such as abdomino-perineal resection of the rectum, nephrectomy, vagotomy, and all operations on the oesophagus and cardiac end of the stomach, and operations on the thoracic and lumbar sympathetic systems.

The set consists of twelve retractors of similar curve but varying length, held together by a folding bolt for sterilizing and until they are needed.

Correspondence

An Unfortunate Precedent

SIR,—To doubt the impartiality of Lord Moran in his capacity as chairman of the Committee for Distinction Awards to Specialists verges on the imbecile; but the letter (April 30, p. 774) published over the names of eight officers of the Royal College of Physicians does indicate a cause for apprehension. Thus (quoting your leading article of April 23, p. 717), they assert that it is insulting to suggest that in future Fellows of the Royal College of Physicians may hesitate to criticize the President lest they be passed over when distinction awards are made.

Of course, such a idea is ludicrous, but it has always been supposed that not Fellows but Members live in the shadow of dangers of such a type; and now their liberty is in even greater jeopardy, because, as the letter from the eight officers suggests, at least by implication, merit awards for physicians will go to Fellows.

Is there anyone so temerarious as to suggest that all Fellows have attained to their glory because of greater professional merit than any Member? I think the answer must be No. It is notorious that luck (perhaps, as many supposed, biased by prejudice) plays an even greater part in elections to the fellowship than in the examination for the membership. In the past this mattered little, except to the *amour-propre* of senior Members; but in the future it will involve financial loss.

Is it not time that the Fellowship of the Royal College of Physicians of London should be awarded for professional eminence, and that it should not be unreasonably withheld from those who have attained the necessary professional position? The present procedure by which a nomination can be held back by the Council and so never come before the Comitia reeks of totalitarianism.

All the Members with whom I have discussed the matter agree with me, but, being less senior than I, fear that the Fellowship will be for ever out of their reach if they become vocal.—I am, etc.,

London, W.1.

A. PINEY.

SIR,—It is surprising to read (April 30, p. 774) that no less than eight officials of the Royal College of Physicians missed the object of your leading article (April 23, p. 717) in which you expressed doubts as to the wisdom of the P.R.C.P. holding the chairmanship of the Distinction Awards Committee. I feel sure few would object to Lord Moran in a personal capacity serving on that Committee on an equal level with his colleagues, and the propriety of such membership was never questioned in your article. The difference between chairmanship and membership of that Committee seems to me to be of the greatest importance, because the holding of the chairmanship as well as the presidency of the College would place him in a commanding and probably an unenviable position. It is not clear whether the eight officials write on behalf of other Fellows and Members of the College or in a personal capacity, but, whether or not they regard the suggestions in your article about favouritism and fear of criticism as a personal insult, it is surely of greater importance that these dangers which many specialists fear are clearly foreseen, and you will no doubt be congratulated by many specialists who are Fellows and Members of this ancient College for pointing them out.

As a Member of the College, it appears to me that the possible dangers that might arise are twofold. First, that while no one, least of all the writer, wants to criticize Lord Moran's sincerity and integrity, which no doubt would be shown as chairman of the Committee, the possibility must be foreseen that the distinction awards may excite criticism and, rightly or wrongly, perhaps a sense of grievance among distinguished aspirants to awards. It does not require much imagination to foresee a condition of affairs arising when specialists become divided up into cliques and undesirable rivalries. Secondly, our position as Fellows and Members of the College is entirely changed directly we become dependent on our fountain-head, the President, for possible financial advancement. Some may

feel that the presidential chair should remain above the level of financial remuneration, and one shudders to imagine the views of our forefathers were they able to survey the situation arising.

Those who have served in the Forces are well aware of the dangers of any form of criticism of superior officers; this is so much realized that no criticism is ever contemplated. It is fear, either conscious or subconscious, which prevents any form of criticism or even undue initiative. On active service such conditions are regarded as a necessary evil. But where they pervade civilian life, and indeed are instituted by the profession itself, it is not surprising that specialists may view the situation with dismay and apprehension. Already by compulsion much of our financial remuneration is subject to the officialdom of the Ministry of Health, and no doubt there are some Fellows and Members who hope that their relationship to the College may not develop on a similar footing.—I am, etc.,

SPECIALIST AND M.R.C.P.

Treatment of Basal-cell Carcinoma

SIR,—The final sentence in the article by Sir Cecil Wakeley and Mr. Peter Childs on basal-cell carcinoma (April 30, p. 737) states that "surgical excision of all rodent ulcers is recommended." I feel bound to challenge so sweeping a statement.

Small basal-cell carcinomata can sometimes be eradicated by a wide variety of therapeutic procedures, but surgical excision and irradiation are the most consistently effective. Patients have no particular bias in favour of a treatment method, and ask only that their tumour shall be dealt with adequately from the first and that they shall be left with as little scarring as possible. The tragedies that still occur with this disease are nearly always due to incomplete excision or inadequate irradiation at the time that the first treatment is given. It is more important that the first treatment should be efficient than that either method should be preferred. Both surgery and irradiation have a useful part to play, but I did not think that anyone who had an extensive experience of the treatment of basal-cell carcinomata would to-day deny that radiotherapy was the more suitable method of treatment for the majority of these patients.

Sir Cecil Wakeley and Mr. Peter Childs give particulars of 27 cases of basal-cell carcinoma occurring at sites other than the face and the scalp, selecting for special mention the uncommon sites where these tumours are more suitable for surgical excision. They give the result in only three of these cases (recurrence-free at 9 years, 4 years, and 2 years) and in none of the other 210 cases referred to where the tumour was situated on the face or scalp. If categorical statements of the kind contained in this article, which contradict accepted practice in most centres where large numbers of these cases are seen, are to be made, they should be backed by a clear statement of fact and not merely by an expression of hope that "there should be no recurrence with adequate surgical excision."

It would require considerable space to take up each point quoted by them in favour of excision—in my opinion some of these are misleading and others are untrue. I agree that recurrence after failure of irradiation is an indication for surgery—unfortunately the recurrences that we see after surgery are not often suitable for radiotherapy. Important considerations of relative cosmetic effect and the occasional need for extensive plastic repair following excision are passed over lightly. Only one concession is made, when it is suggested that in some cases of multiple superficial lesions irradiation may have practical advantages over multiple excisions. Shortly afterwards the really dreadful sentence, "Only rarely need a patient be condemned to irradiation on account of poor health," occurs. What kind of radiotherapy can they have seen? To take only one common example, patients with basal-cell carcinomata of the eyelids have generally a better chance of cure and less deformity with irradiation than with surgery, quite apart from "less time lost from work, admission to hospital, and mental trauma," which, in these cases at least, are wrongly claimed as surgical advantages. "Mental trauma" is surely special pleading—at least I have never had to give "premedication" to my patients with rodent ulcers "to diminish their worry."

The following table is presented to show the results obtained with 474 patients treated by x rays up to the end of 1944, and to indicate what has been done with one method of radiotherapy.

The policy of treating the majority of these tumours by radiotherapy when they occur on the face, neck, or scalp, and of excising most of the solitary ones that occur elsewhere, as well as those few which fail to respond to irradiation, has resulted in the eradication of the disease in nearly all the previously untreated patients whom I have seen since 1935. I know of only one which persisted and contributed towards the patient's death, and this, treated by both surgery and irradiation, was extensively involving bone when the patient was first seen. This may, of course, have also happened in some others which were lost sight of during the war and which we are now

Results of Treatment by X Rays of New Cases of Basal-cell Carcinoma, 1935-44

	No. of Cases Treated	Lost Sight of	Died of Intercurrent Disease	Recurred	Recurrence-free	Percentage free from Recurrence
Patients treated more than 10 years ago, 1935-37	68	21	9	3	35	92
Patients treated more than 7 years ago, 1935-40	256	69	56	18	143	89
Patients treated more than 5 years ago, 1935-42	368	72	57	27	212	89
Patients treated more than 3 years ago, 1935-44	474	89	49	36	300	89

One old lady died of intercurrent disease with some residual tumour present, and one died with an active growth which hastened her death. All other patients whose tumours recurred were re-treated by surgery or irradiation and were disease-free when last seen.

trying to trace. The table needs to be brought up to date, but the available facts are there to be examined and interpreted; every known recurrence, however trivial, is included, even if dealt with successfully by further irradiation.

A number of other large series of patients with rodent ulcers treated by radiotherapy have been published in recent years. If surgical excision of every rodent ulcer is to be recommended, it is desirable that the facts on which this recommendation is based be presented for assessment and comparison.

Surgical excision and irradiation are both available for patients with rodent ulcers; a judicious selection of the method or combination of methods best suited to each individual patient produces not only freedom from recurrence but excellent cosmetic results as well. Surgeons and radiotherapists do better by working together than by claiming exclusiveness.—I am, etc.,

Resection of the Fallopian Tube

SIR,—Lately, after salpingostomy, instead of inserting catgut to keep the tube open I have been using a thin strip of oxycel. I have only done this in a limited number of cases, and they are too recent to be able to forecast about pregnancy, but the x-ray reports have been satisfactory with regard to patency.

I am not sure if this is an original procedure, but I have not seen a note of it elsewhere.—I am, etc.,

Dublin.

BETHEL SOLOMONS.

Statistics and Health Education

SIR,—Dr. F. Gray's letter (April 16, p. 680) brims over with ideas—some very good—but he has not subcultured and isolated the better ones for close and critical analysis. He appears to chafe unduly at the prevailing practice among public-health workers of collecting and examining morbidity statistics before taking preventive action in certain fields. Inquiry, sorting, and computation are as necessary prelude to the logical planning of prophylactic measures as diagnosis is to treatment. His suggestion that "the problems of real life" would be solved by subsidizing selected general practitioners to under-

take research into these problems can surely, if carried out, get us no further than to convert this *crème de la crème* of G.P.s into clinical specialists or social statisticians—very good in itself but not really what Dr. Gray and I are aiming at.

Let each cobbler stick to his most accustomed last. Let the Ministry of National Insurance (and any others who can and care to) collect and publish morbidity statistics; let G.P.s (and others) treat the sick and discover and make known the intimate social pathology influencing recognizable physical and mental disorders. Then Dr. Gray may leave the health educator to use this (and other) information and to ascertain where, among which sections of the community, and on what aspects of health and disease ignorance is most manifest. In this way health instruction to the laity can be most appropriately and effectively planned.

Dr. Gray asserts that "attempts at preventive medicine are being made in a sort of vacuum—hence their ill success." The disappearance from this country of leprosy, typhus, malaria, plague, and cholera; the considerable diminution in smallpox, typhoid, scurvy, rickets, tuberculosis, and diphtheria; together with the progressive decline in the mortality rates for all age groups, and especially among infants, are apparently among the forgotten achievements of applied preventive medicine. I suggest that any remaining "vacuum" can be filled by accurate social and medical statistics. Well-conducted sample surveys among most types of community will yield reliable data on the prevailing needs and will provide a measure of the effectiveness of health education measures. Health education of the individual is not quite the same matter as teaching health to community groups. They are related subjects but based on different criteria (statistics), and each calls for a separate technique.—I am, etc.,

London, S.W.1.

W. HARTSTON.

Food, Health, and Education

SIR,—It is now known that the streams of advice and information upon the choice and the cooking of food to which since 1940 the Ministry of Food has treated the housewives as to be strained into a melting-pot and left to simmer awhile. Some of the work will be taken over by those of the local education authorities who are sufficiently interested to find place for it; and the Ministry of Food will apparently be maintaining a small central staff and a dispersed body of voluntary "food leaders," whose real activities have never been precisely assessed. Presumably the Ministry will also continue to use the Press and radio.

So long as the conditions of supply and rationing were liable to abrupt changes it was natural that the task of instructing the public should fall to the Ministry of Food, for, after all, no other Ministry could have handled the shifting situation. But it is now pertinent to ask what part the local health departments will be expected to play; and it is no less necessary to point out that the country is faced with some serious and interrelated problems in the nutritional field of public health. The time has come to take stock of what is in the melting-pot then we had better decide what kind of educational brew is needed.

The advice services initiated by the Ministry of Food were plainly intended to shepherd the housewife through the complexities of wartime rationing. But the quality of the problem has now changed; and this change in quality is best summarized under three propositions: (1) The published figures suggest that the average diet has been remarkably well balanced on a day-to-day basis; that is to say, while there has been certain element of monotony, the constituents of the diet have somehow combined to sustain a reasonable level of staminal and a good growth record. (2) But a shift in the proportions of supplies (e.g., more sugar and less meat) might have the effect of throwing the average diet out of balance, and it is difficult to see how this is to be prevented in a free community except through a process of education. (3) Even more important is for us to face the fact that what we believe to be our traditional pattern of diet may have passed away for ever. The typical British diet of 1970 may, in brief, have to be something very different from the typical middle-class diet of 1930 (which was presumably the standard most working-class families would have aimed to reach if their means had permitted).

ON GUARD in tinea territory

Activity is on the increase in swimming pools, baths and other centres of communal activity where the organisms responsible for mycotic infections find their hosts. Key measures to efficient control of such infection are prompt treatment of the developing case and planned protection among likely contacts . . . and in both roles Mersagel is equally effective. Mersagel contains the powerful fungicide, phenylmercuric acetate, in a special water-soluble jelly base. It acts directly against the infecting fungi and maintains intimate contact with the seat of infection. Colourless and therefore clean to use, Mersagel does not normally irritate the skin and is suitable for the patient's personal application.

In 1½ oz. tubes & 16 oz. jars

Phenylmercuric acetate (1:750) in a water-soluble jelly base

For sustained control of gastric hyperacidity

NOVASORB

(Hydrated Magnesium Trisilicate)

Novasorb provides for sustained control over gastric hyperacidity without producing an alkaline condition in the stomach. It thus presents a desirable improvement over the older antacids, where control is limited to the immediate reaction and where continued administration of excess alkali may induce alkalosis.

High adsorptive properties

Will not give rise to alkalosis

With suitable doses, does not destroy peptic activity

A safe antacid for general use

The Novasorb brand of hydrated magnesium trisilicate was developed and introduced by Evans Fine Chemical Works and is based on original observations and clinical trials (*Brit. Med. J.*, 1936, 1, 143, 205 and 254)

Issued in Powder and Tablet form

An anti-histamine of wide application

HISTOSTAB is one of the most satisfactory antidotes for histamine now available.

In the treatment of a wide range of allergic conditions Histostab has few undesirable side-effects. It may be given orally, or by injection when rapid action is required. It will control allergic urticaria and eczema, and will relieve the itching in certain cases of pruritus. It has proved of value in cases of sensitivity to Insulin, Liver and Penicillin, suppressing the unpleasant effects and allowing treatment to be continued.

As Compound Solution of Histostab it is available for nasal and ocular instillation in vasomotor rhinitis and hay fever.

Histostab Tablets. Bottles of 25 x 0.1 G. tablets.

Injection of Histostab. Boxes of 6 ampoules of 2 ml. (0.1 G.).

Solution of Histostab Compound. Bottles of $\frac{1}{2}$ fl. oz.

CPL

It is no longer a matter of persuading a people to adjust itself to the vagaries of wartime rationing. The concept we need is that of a long-term process of formal and informal education in components of which are integrated into a continuous scheme. The problem has become less administrative or purely educational than medical. It concerns neither the worries of the Minister of Food nor the natural wish of a few people to attend classes on cooking and food management; it concerns the subtle and elusive question of the precise part played by a balanced diet in maintaining and improving health and working capacity. For this reason it is, in some measure at least, an affair of the Ministry of Health and of the local health authorities.

What are the elements in our present diet that have combined to give it balance? We can only surmise; but if we prefer to rest on the safe side we may mention the larger and far more even consumption of milk, the provision of welfare foods, the highly milled flour, the higher (though still inadequate) consumption of vegetables, the higher consumption of potatoes, the restricted consumption of sugar, and, finally, a trend towards the made-up or "mixed protein" type of dish in place of the undary roast followed by a week of scraps, cereal products, and oddments. Physiologically it is the day-to-day fare that matters, not the total components of a dietary as estimated over the course of a week or month. Nutrition is a continuous process. And while an occasional feast day and an occasional period of austerity clearly make for most consumers very little difference, one may assume that the nutritional level is better maintained where the day-to-day or even the meal-to-meal diet is a soundly balanced one.

Partly by luck and partly by judgment the people of this country have been since 1939 manoeuvred closer and closer to a dietary that approximates to what we should approve. Can they be persuaded to stay there and to make further progress? Now, if the task of instructing the public on food matters is to be divided between the Ministries of Food and Education, there is a certain risk involved. The Ministry of Food may tend to view the task, so far as it retains its powers, as merely a continuation of its wartime activities and not to appreciate the change that has come over the quality of the problem. The Ministry of Education, on the other hand, may tend to concentrate on the provision of more or less formal classes under its scheme of adult education; and it is evident that such classes, indispensable as they are, do not reach more than a very limited section of the housewives of the country. Such classes were in any case normally provided before the war by a number of the education authorities, and we should merely have an extension of the same practice without due consideration of the urgent medical problems with which we are now faced.

It is surely desirable that someone or some committee should intervene. What we need is a careful and objective assessment of the real effect of the "advice" work of the Ministry of Food and the outlines of a broad scheme of formal and informal instruction and advice that will gradually leaven the thoughts of the consuming public over a term of years or even of generations. It should be the aim of any community to make each generation better nourished than was its predecessor, and that is partly a matter of food supplies and greatly a matter of education. But the leaven must begin its work in the schools and influence every age and condition of life. A scheme of this nature cannot necessarily be implemented without delay—patently in present circumstances it could not—but that is no reason why it should not be foreshadowed in broad outline.

If the intervention comes, it should be medical; and preferably it should be extra-ministerial. Not that the Ministries are unfitted to look after their own affairs, but this is a case where the public interest would be best served by a frank, inclusive, and unhurried review of all the complex factors involved.—I am, etc.,

Oxford.

F. LE GROS CLARK.

Treatment of Rheumatoid Arthritis by Vasodilatation

SIR.—The results of treatment for rheumatoid arthritis have remained unsatisfactory. Recently a number of therapeutic measures have been tried, all attempting to produce increased blood supply to the diseased joints. Thus spinal pumping, blood and plasma infusions, and intravenous T.A.B. injections

have been given to promote vasodilatation. It is possible that the remissions caused by jaundice and by infusions of blood from pregnant women are also caused by improved blood supply to the diseased joints. The ordinary physiotherapeutic measures, such as radiant heat, wax baths, short-wave diathermy, etc., as a rule only given for short periods, also aid in increasing the circulation of blood in the joints. The usually short-lived benefit is probably based on this factor.

All these methods have only a temporary effect. We therefore sought for means of applying heat to the body which would be well tolerated by the patient and would produce sustained vasodilatation. The method we adopted is the application of a large electric blanket to the lower half of the body. The patient's feet, legs, and pelvis are well protected by sheets of cotton-wool bandaged on to the limbs and body. The electric blanket is then wrapped round the patient and kept in position by bandages. The blanket is left in position for prolonged periods—up to four weeks in some cases—and the patient only taken out of it for toilet purposes. The temperature between the cotton-wool and the blanket is between 108° and 110° F. (42.2° and 43.3° C.). This type of application of heat produces generalized vasodilatation with pronounced sweating. The resulting fluid and salt loss is made good by additional fluid and salt intake. A fluid intake and output chart is kept and a check made on the chloride excretion in the urine.

The patients tolerate this treatment well. We have treated eight patients so far, mostly cases suffering from advanced rheumatoid arthritis with severe joint deformities and marked limitation of movement. In every case the improvement was marked. The range of movement is increased, the swellings subside to a large extent, and the stiffness and pain also improve considerably. Three women, whose hands had been fixed for five years, after three weeks' treatment were able to knit again. Since the patients so far treated have all been advanced cases, a complete cure could hardly be expected. Although improvement appears to have been maintained it is impossible to say at this stage whether further relapses may occur, and it is therefore suggested that this method is tried out at a special centre on a number of patients who could be followed up carefully. We have no doubt that this treatment is more promising than other measures which are at present available. An additional advantage is that this treatment can be given to the patient in his home under the supervision of his own doctor.

We feel that the electric-blanket treatment should be given a wider trial and be used experimentally in conjunction with other methods at our disposal for increasing the blood supply to the diseased joints—for instance, plasma and blood transfusions, nicotinic acid infusions, the administration of tetraethylammonium bromide, sympathetic block by injecting the sympathetic ganglia, and gold or vaccine therapy.

We have approached the makers of the electric blanket to make us special trousers, which include the feet, out of the material, since such an appliance could more easily be kept in position and also allow for nursing purposes. The electric-blanket method of producing vasodilatation may be also useful in other conditions in which a constant increase in the blood flow to certain areas is beneficial.—We are, etc.,

ERIC FRANKEL.

London, E 11.

D. LANG STEVENSON.

Vaccine Treatment of Rheumatoid Arthritis

SIR.—My old chief, Sir James Kingston Fowler, used to say that every new remedy of value is recognized as such by the profession within six months of its introduction. One has only to think of antiphotphoric serum, salicylates for rheumatic fever, salvarsan, insulin, liver therapy, the sulphonamides, penicillin, radiotherapy, and E.C.T. to realize how very true this aphorism has proved itself to be.

But what about treatment with vaccines? This was first suggested, I think by Sir Almroth Wright, about forty years ago. It was used for diseases of infective origin—furunculosis, typhoid fever, *Bact. coli* infections of the urinary tract, and (as tuberculin) for tuberculosis. In each of these success should have been certain, for the vaccine was specific, but it had to be confessed that in each case the treatment was useless, if not indeed harmful.

In rheumatoid arthritis, however, most astonishingly, vaccines are still employed. Here is a disease, or group of diseases perhaps, of unknown aetiology which, upon a hypothesis unsupported by evidence, is being treated with complex chemical bodies whose action is not known and which have never been proved to be of more value than boiled tap water. After years of consistent failure and disappointment many hours of time and hundreds of pounds are still being wasted every year upon their preparation and administration. Perhaps even more significant is that the ideas underlying their use obstruct the introduction of new conceptions.—I am, etc.,

Beckenham, Kent.

W. MAXWELL PENNY.

Perforation of Gastric Carcinoma

SIR,—Mr. Louis A. Ives's edifying communication (April 30, p. 758) touched on an exciting topic, but may give a rather pessimistic impression to young surgeons.

On May 5, 1938, I operated on a man, aged 55, for perforation. It came "like a bolt from the blue" when he, a publican, was seized with agony while serving in the bar, and called his doctor, who rushed him to the nursing-home. To my surprise a mid-lesser-curve ulcer, obviously cancerous, was found with a large hole in it. Partial gastrectomy was undertaken forthwith. Smooth healing followed. Biopsy by Dr. A. D. Fraser confirmed carcinoma.

This may seem bold surgery, but the patient was seen on April 12, 1949, by his doctor and found perfectly well—11 years later. I am only sure of three other patients of mine with gastric cancers (non-perforated) surviving over 10 years after operation.—I am, etc.,

Bristol

A. WILFRID ADAMS.

SIR,—Perforation is not a common complication of carcinoma of the stomach. Mr. Louis A. Ives's case (April 30, p. 758) emphasizes the need to be on the look-out for the condition in apparently straightforward perforations.

A similar case was recently admitted to Lymington Hospital. The patient, a man aged 54, was admitted on April 26, 1947, with a typical story of a perforated peptic ulcer of four hours' duration. He gave a history of many years' dyspepsia, for which he sometimes took alkaline powders, but he ate a fairly full diet. He had never previously been in hospital. At operation a perforation $\frac{1}{2}$ in. (0.6 cm.) in diameter was found in the pyloric antrum. This was closed with a plug of omentum. The ulcer had a wide proliferating margin which could be felt through the stomach wall. It was considered to be malignant, but a gland removed for biopsy showed no malignant invasion. Convalescence was uneventful.

In view of the operation findings, gastrectomy was performed on May 20, 1947, and microscopy of the ulcer confirmed the diagnosis—extensive adeno-carcinoma and simplex carcinoma." He made a good recovery from the operation and was discharged from the hospital on June 14, 1947. When seen later in the year he was free from symptoms and back at work as a chauffeur, and he ultimately left the district. However, in April, 1948, I heard from his doctor in Northampton that he had had a recurrence and died shortly afterwards.

The interval of three weeks between the operations is convenient, as the patient has time to get over the shock of his perforation but the growth has not long to extend; nor is there time for the gastrectomy to be complicated by well-established adhesions.—I am, etc.,

Lymington, Hants

GEOFFREY ST. J. HALLETT.

The Treatment of Tetanus

SIR,—I would like to question the remarks of Drs. M. H. Armstrong Davison and A. B. Ward and Professor E. A. Pask (April 9, p. 616) concerning the value of penicillin in tetanus. It would seem logical that if the toxin elaborated by *Cl. tetani* can reach the blood stream, then penicillin can diffuse to the responsible bacilli. If the latter were completely shut off from the blood stream there should be no clinical problem. It would be sounder to argue that it is unlikely that further toxin, formed after the massive intravenous injection of antiserum, would reach the central nervous system unneutralized. While admitting this argument, I still believe that heavy dosage with penicillin is indicated as an adjunct to the other treatment in order to suppress the responsible organisms, not merely as a prophylactic against respiratory infection.

As far as treatment with curare is concerned, I too have encountered the same respiratory embarrassment, and it would seem that "myanesin" is the present drug of choice. In a case currently under treatment with curare (myanesin not available) the patient was much distressed initially by saliva and mucus in mouth and throat—so much so, in conjunction with the respiratory difficulties, that the question of tracheotomy was seriously considered. At that time I was giving *d*-tubocurarine by intermittent injection into the tubing of an intravenous drip, but in view of the mucus production it was thought wiser to restrict fluids. I have since been injecting the curare intermittently through a short lumbar-puncture needle, with stylet, left in the vein. This does not interfere with the patient's movements and requires little attention. While not an ideal aseptic procedure, it spares the patient from repeated needling and ensures the instant availability of a vein.—I am, etc.,

Victoria, British Columbia.

JAMES FIDDESS.

Physiology of the Orgasm

SIR,—I am obliged to Dr. P. D. Eeman for his letter (April 2, p. 593) drawing attention to my Reichian assessment of the physiology of the orgasm as published in my book *Clinical Psychology*, though I think it would have been more polite as well as more accurate to call my remarks "incomplete" rather than "incorrect."

Dr. Eeman's quotation is also naturally incomplete. In the following paragraph (p. 95) I say, "... It seems from this patient's experience that an anxiety discharge can actually produce relief of tension comparable to that of an orgasmic discharge. Perhaps this discovery is not so strange when we reflect that many a woman speaks of a 'good cry' as a relief for her pent-up emotions." Surely this is at least indicative that I consider that the orgasm may be regarded as "a brief period of acute sympatheticotonia occurring at the end of a period of parasympathetic predominance," and that my view is therefore not contrary to that of "Kuntz, White, and Smithwick."

Although my book is in no way devoted to the physiology of the orgasm I still think that it is impossible to give too much attention to the details of this much neglected psychophysical phenomenon. The stress laid on abreaction by every form of psychiatric treatment, mental and physical, should remind us that there is a perfectly normal form of abreaction provided by Nature for the maintenance of optimum intrapsychic tension.—I am, etc.,

London, W.1.

G. CHARLES BERG.

B.C.G.

SIR,—Dr. W. Norman Taylor in his letter about B.C.G. (April 30, p. 778) is rightly anxious for facts about the efficacy of vaccination; Professor W. H. Tytler's recent article¹ and the "Memorandum on B.C.G." produced by a joint committee of the Tuberculosis Association and the Joint Tuberculosis Council (1946, London) both give excellent summaries of the evidence. He is also afraid that we may "get carried away in our enthusiasm for spending large sums on B.C.G. vaccine." In a country that has adopted a waiting policy for 25 years there is little danger of this.

But it is less clear why he thinks that we are "playing with fire" until the efficacy of the vaccine has been proved, or that experiments to test its efficacy should be conducted "with full realization of the risks involved"; these are questions of safety, not efficacy. With the global figure of vaccinated standing at ten million (excluding the figures from Japan),² the safety of the vaccine is no longer in question.—I am, etc.,

- ¹ *Medical Annual*, 1948, Bristol, p. 32.
- ² Rosenthal, S. R., *Amer. Practit., Phila.*, 1948, 2, 462.

SIR,—Dr. W. Norman Taylor (April 30, p. 778) asks what are the facts about B.C.G. Until we have some really convincing proofs, he says, let us remember that we are playing with fire. Dr. Taylor must be familiar with the investigation by Hyge, quoted by Wallgren,¹ of an epidemic of tuberculosis in a girls' school due to exposure to an infected teacher. Of

05 pupils tuberculin-positive before exposure, two fell ill; of 06 vaccinated with B.C.G., two fell ill; and of 94 tuberculin-negative, 41 fell ill—morbidity rates of 1.9%, 1.9%, and 43.6% respectively. Is this not proof?

He speaks of playing with fire. Malmros² states that, using Vallgren's method of vaccination, small abscesses occur in .8% of cases and large abscesses in 0.8%. Is this playing with fire?

There seems no reason why tuberculosis could not be wiped out in civilized countries, and it is good news that experiments with B.C.G. are to be carried out here, though it is difficult to understand the necessity for these. The time for experimentation was surely 20 years ago, and the grudging attitude adopted in this country towards B.C.G. can only be considered due to its having been discovered elsewhere, or to inability of the medical profession in this country to appreciate a conception that depends on prevention rather than on treatment.—am, etc.,

Tavistock, Devon.

Treatment of Varicose Veins

SIR,—I must protest, with due respect to Mr. R. Rowden Foote (April 9, p. 635), that ulcer of leg cannot really be treated as one affliction harsh enough to warrant certain measures in treating varicose veins, for any relationship that may exist between ulcer and varicose vein has yet to be demonstrated. It is true the notion of varicose ulcer is of hoary antiquity (Mr. Foote will perhaps have looked into the temple papyrus, 200 B.C.); nevertheless it is but an easy-going repetition founded on no more than too hasty observation, and the notion dodges our incomplete knowledge of the aetiology of ulcers of the leg.

A proper follow-up after treatment and proper control comparisons of thus treated and thus untreated cases of leg ulcer accompanied by varicose vein, at all ages, will show that destruction of the varicose vein, by whatever method, has had no effect on the healing or extension of the ulcer nor on its recurrence. Of course, waiting—over some years perhaps—or this evidence, rendered reliable because cross-examined by time, follow-up, and controls, is tedious. But after all there are the immediate commonplace facts: that the great majority of patients with varicose veins, at all ages, have and have had no leg ulcers, while the great majority of patients with leg ulcer, at all ages, have and have had no varicose veins; that in clinical features, under all conditions, there is no discernible difference between ulcer with, and ulcer without, varicose veins; that Providence affords us often enough the spectacle of one human of chronic recurrent ulcer in one leg, and the only varicose vein (long-standing and down to the malleolus) in the other, and otherwise healthy, leg; that the ulcer, for its part, has no effect on its companion varicose vein, however close the proximity. I note that Mr. Foote's tale of dreadful ulcers in the varicose clinic could not be enlivened by a story of thrombophlebitis of a varicose vein set up by its septic ulcer, or of a sloughing ulcer eroding into its varicose vein. Why not?

I recorded my observations on the danger of a chain-reaction-like necrosing, not sclerosing, thrombophlebitis. Mr. Foote would avoid this by diminishing his dose of sclerosant, while risking starting it by his proper prior scarification of the venous intima.—I am, etc.,

London, W.1.

H. M. HANSCHALL.

Pain in Childbirth

SIR,—While fully agreeing with what Dr. Grantly Dick Read says (April 16, p. 651) about fear underlying most of the discomforts of childbirth, I would like to point out how much needless pain is caused by our neglect of the mechanical factors involved in the process. It seems very strange that Newton and his apple and his deductions therefrom are disregarded in the obstetric world of to-day. The chief cause of unbearable pain connected with a normal birth depends so much on this neglect of his teaching—that bodies fall to the earth by their own weight.

If Newton had laid his tree on the ground how could his apple fall? The child's weight (7 lb. odd) accomplishes the delivery and numbs the parts as it is born by the uniform pressure it exerts on the nerve endings in the stretched and distended perineum, but is it allowed to do so? No. The mother is laid upon her side and now has to supply the seven pounds of propelling force from her own muscles. Furthermore, because she is laid on one side, the left, it is thus put out of action, is kept rigid, becomes congested, and easily torn. I think it will be found that nearly all tears whether of cervix or of perineum are on the left.

Like using a bedpan, the act of excretion becomes difficult when lying down. Normal childbirth became both difficult and dangerous when the lying-down position became general; it is so contrary to Nature. During the war, in using the natural position for childbirth—squatting and kneeling—the members of the antenatal class at Paddington were offered the choice of having an anaesthetic or of seeing their baby born. All chose to see the baby born—and did not regret it. Several of the mothers, all primigravidae (one over 40), volunteered the statement that as the foetal head was passing the vulva they felt no pain down there, but only suffered pain from the contractions in the abdomen.

When the child is being born with the mother kneeling or squatting the pelvis is delicately balanced upon the heads of the femora and can move backwards and forwards on the hip joints, thus keeping the plane through which the foetal head is passing parallel to the ground and ensuring equal pressure on all parts of the muscular opening. At the same time the sides of the pelvis lift (just as the ribs lift in inspiration), the pubic arch widens, and consequently the outlet of the pelvis broadens. Simultaneously the perineum is stretched transversely, and as the mother rounds her back for the expulsion it is relaxed antero-posteriorly as the tip of the coccyx comes forward. When all is thus ready, the weight of the child brings it through the birth canal quickly and with a minimum of suffering to the mother.

A class in which birth is prepared for by exercise and is looked upon as a test of nerve and courage never fails to find recruits who ask for no anaesthetic but long to see their baby born.—I am, etc.,

London, N.W.11.

KATHLEEN VAUGHAN.

Curare-modified E.C.T.

SIR,—The technique of curarization propounded by Drs. Peter D. W. Shepherd and David C. Watt (April 30, p. 752) must in the following particulars be called into serious question.

(1) Their recommended initial dosage of 2.5 mg. per stone (6.35 kg.) for females and 3 mg. per stone for males is dangerously high. They have never, they say, seen a case unduly sensitive to curare. If they had, their technique might well have led to consequences more severe than the prolonged apnoea of a number of their patients, as a fairly recent article in the *Journal* (April 24, 1948, p. 784) by Gray and Halton portends. These authors not only counsel a maximum initial dose of *d*-tubocurarine chloride of 15 mg., but advise also a trial dose of not more than 5 mg. followed by a watching period of two minutes. They cite a fatal case of respiratory arrest after the administration of 15 mg. of *d*-tubocurarine chloride and 0.5 g. of thiopentone, and a case showing apnoea with diminishing doses of *d*-tubocurarine chloride—indeed, with as little as 2 mg. at the third induction. Yet Drs. Shepherd and Watt would submit a man of 10 stones (63.5 kg.) to an initial curarization of 30 mg., and a 10-stone woman to one of 25 mg.

At the Warneford and Park Hospitals my technique at first curarization is to give 5 mg. of *d*-tubocurarine chloride at two-minute intervals until a total quantity has been administered sufficient to prevent any movement of the upper arms and forearms except forearm flexion. Adequate muscular relaxation without severe respiratory depression results. The full dose thus calculated can be rapidly administered at reintroductions without harm. Moreover, this technique has failed to demonstrate any exact correlation between the patient's weight and the needed dose of curare. Thus a male patient weighing 9½ stones (60.4 kg.) required a maximum dose of 15 mg. of *d*-tubocurarine chloride for excellent relaxation; another of 15 stones (95.15 kg.) never needed more than 25 mg. Drs. Shepherd and Watt would presumably have almost doubled these doses at the first induction. On the other hand, a frail man weighing 7½ stones (47.6 kg.) required 35–40 mg., and Case 43 in Drs. Shepherd and Watt's series showed an even greater tolerance.

It is therefore submitted that it is dangerous to calculate the initial dose of *d*-tubocurarine chloride by weight alone, particularly at so high a value as that employed by Drs. Shepherd and Watt. The above-described technique of small doses slowly administered obviates all danger of fatal drug sensitivity.

(2) I can see no rationale for the technique described by Drs. Shepherd and Watt of mixing *d*-tubocurarine chloride with thiopentone and atropine, if I have understood them correctly. In the first place it alters the amount of fluid in which each drug is dissolved, complicating calculation. Secondly, it prevents variation of one drug without a proportionate variation in the others. Yet it is as important to reach by calculation the correct end-point with thiopentone as it is with curare.

My technique with thiopentone is to give the drug at a steady rate of about 0.1 g. every five seconds, making the patient count rapidly, and to stop the injection as soon as the patient's voice starts to tail off. In this simple way unconsciousness with the minimal amount of thiopentone is achieved. To do this effectively it is essential for the thiopentone to be administered separately from the curare, although through a single venepuncture. For in-patient therapy it has been found most simple to give a standard dose of atropine, 1/75 gr. (0.9 mg.), subcutaneously 1½ hours before treatment, as is done pre-operatively.

(3) Drs. Shepherd and Watt have had little use for neostigmine, while, it appears, tolerating apnoea in their patients of up to 45 minutes. Patients begin to come round from the post-convulsive coma in 5-10 minutes. There can surely be no justification for submitting a patient to the distress of waking up weak and apnoeic, and one's staff to the needless imposition of continuing artificial respiration for up to 45 minutes, when a routine intravenous dose of "prostigmin" (1½-2 mg.), given immediately upon cessation of the convulsion, so rapidly and effectively abolishes the curare-effect that artificial respiration, in my experience, can invariably be discontinued directly after the injection, and no patient wakes conscious of having been curarized.

—I am, etc.

Oxford

S. J. G. SPENCER.

Transfusion Compatibility Tests

SIR,—The commonly employed direct compatibility test, using the patient's serum and a saline suspension of donor's cells, is unsatisfactory and dangerous. The transfusion reaction described by Drs. A. C. Buchan and John Wallace (April 16, p. 660) illustrates the danger attending its use, and emphasizes the absolute necessity of using a compatibility test that will detect incompatibilities due to Rh and other irregular agglutinins, both of the saline- and albumin-agglutinating types.

The application of the indirect Coombs test would probably provide the greatest safety, for it is apparently the only test that detects the rare cryptagglutinoids, but it seems too laborious for routine use and too involved for many who might have to perform urgent cross-matching. In this laboratory saline suspensions are never used, all compatibility tests being performed with albumin suspensions by the open-slide method of Diamond and Ableson. For the past six months we have simplified our arrangements for this test, so that it can be easily performed by anyone wishing to cross-match in the absence of laboratory staff. Our procedure is as follows:

Blood in the citrated pilot tubes, supplied attached to the bottle, is allowed to settle, and two drops of the sedimented cells are transferred aseptically to sterile plugged tubes (2 × ½ in.; 5 × 0.9 cm.) containing two drops of 30% bovine albumin; care is taken not to include any supernatant fluid. These small tubes are fixed to the pilot tubes with adhesive tape. All blood is treated in this way before being made available in the "bank."

Compatibility is tested for by mixing equal volumes of this albumin suspension and the patient's serum or plasma on a slide and reading after 15 minutes in a 37° C. incubator or over a lamp—precautions being taken against drying. Advantages are that the suspension is ready for immediate use and no additional reagents are needed.

Specific agglutinability is retained for at least 10 days; we have made no tests over a longer period. Owing to the optical properties of albumin the cells in the tubes may appear haemolysed although they are well preserved.

Dangerous reactions are likely only in the presence of pre-formed agglutinins. The use of a satisfactory compatibility test is therefore a more important safeguard against dangerous reactions than is routine Rh testing with a limited range of sera, for only in this way can the reactions due to the rarer Rh antibodies and other irregular agglutinins be avoided. A test on the above lines can provide a considerable measure of safety; it remains only to convince all those prescribing blood of the inescapable obligation of employing a compatibility test.—We are, etc.,

Pathological Department
North Staffs. Royal Infirmary, Stoke-on-Trent.

B. GODWIN.
A. J. McCALL.

Routine Medical Examinations

SIR,—A conference was recently held under the auspices of the British Council for Rehabilitation on "The Problem of the Cardiac Patient in Industry." One of the principal speakers inferred that the routine medical examination of individuals in industry had very little value except for the supervision of special cases under specialist direction. He spoke, perhaps unintentionally, with something of the disdain of a certain type of specialist for anyone not equipped with specialist training and a battery of scientific apparatus. The specialist has been described as one who knows more and more about less and less, and certainly many specialists know far too little about the indivisible problem of health as opposed to the specific classification of disease. The specialist too often is concerned primarily with cure and salvage, after neatly fixing a label.

The doctor in industry, as team-mate of the general practitioner, is concerned with very different problems—how to help people to keep out of range of the specialists by promoting health and preventing disease. The value of the routine medical examination is not primarily to detect disease. The good doctor has to develop a fine clinical sense in conjunction with knowledge of men and a sound training in examination and the taking of a full history. This enables him to select a certain proportion of cases for reference to their G.P., and a smaller number of these are sent for detailed investigation by the specialist. Often the cases are sent to him not so much for his advice as for the special investigation by apparatus which the ordinary doctor has not at his disposal. Such cases would otherwise come forward at a much later stage in their disease.

This is only a very small proportion of the cases seen by the industrial doctor. Primarily, I think, the value of routine examinations lies in reassurance, guidance, and general health education. In every consultation the doctor learns something of human nature, and may have an opportunity of using his knowledge for the aid of his patient.

We hear much to-day of the stress diseases which cause such vast national loss. The industrial doctor is in the front line in the study and prevention of these diseases, which owe so much to bad mental hygiene and disharmony of interpersonal relations. In this capacity he is a catalyst in industrial affairs. Beyond this, the routine examination gives great opportunities for the study of the natural history of disease and the practice of social medicine. If improvements are to be made much will depend upon the quality and the philosophy of those who guide the development of students into doctors. In this role, is it too much to say that the specialist has perhaps his greatest opportunity, for good or ill, as the teacher and ultimately the support of the front-line doctors?—I am, etc.,

Farnham Royal, Bucks.

M. E. M. HERFORD

POINTS FROM LETTERS

Diet in Disseminated Sclerosis

Dr. C. D. Ross (Stafford) writes: The study of the geographical distribution of disease has brought to light many important facts in its aetiology. It has been pointed out by Snapper (*Chinese Lessons to Western Medicine*, 1941, New York) that arteriosclerosis occurs rarely in Northern China, in spite of the fact that diabetes is common. He suggests the fundamental differences in dietaries to be the underlying cause of this phenomenon. It is known that the Chinese diet contains only small amounts of cholesterol but considerable quantities of unsaturated fatty acids, especially linoleic and linolenic acids. From the available literature it is found that disseminated sclerosis is rare or absent in China, where the staple diet is rice. It would appear that disseminated sclerosis, as well as arteriosclerosis, is connected in some way or other with diet and metabolism. Would it be wishful thinking to assume that in a case of disseminated sclerosis the substitution of an average Chinese diet would prevent the further ravages of the disease?

Diathermy Prong Forceps

Mr. A. WILFRID ADAMS (Bristol) writes: I am grateful to Mr. David Aiken (April 30, p. 780) for giving his further experience with diathermy devices for haemostasis. They will help in emergency, but do not allow me to dispense with a pattern specially designed and correspondingly efficient. The prong forceps never fails me, and is a well-warranted adjunct which is in incessant use when operating.

Obituary

G. SECCOMBE HETT, M.B., F.R.C.S.

Mr. Geoffrey Seccombe Hett died suddenly in London on May 3, at the age of 70. He received his medical education at University College Hospital, where he qualified in 1903. He graduated M.B. a year later and went on to take the F.R.C.S. in 1908. Before finally settling down to consulting practice as an ear, nose, and throat specialist, Hett undertook postgraduate study in this specialty in several European centres, including Vienna and Freiburg. He was appointed assistant surgeon for diseases of the ear, nose, and throat at University College Hospital in 1912 under the late Mr. Herbert Tilley. He was also at different times on the staff of the Throat Hospital, Golden Square, the Royal London Ophthalmic Hospital, Mount Vernon Hospital, the Cassell Hospital for Nervous Diseases, the Ear, Nose, and Throat Hospital at Eastbourne, and the Cottage Hospital, Cranleigh. During the first world war Hett served in the R.A.M.C. with the rank of major, and was at one time officer-in-charge of the Middleton Park Convalescent Hospital for Head Injuries. He became interested in the plastic repair of facial, and especially nasal, injuries, and was for some time attached to the facial injuries centre at Sidcup. Sir Harold Gillies, with whom he worked here, said that his work on nasal injuries was outstanding.

Hett soon achieved a large consulting practice, and attended members of the Royal Family on more than one occasion. He was a fine operator, a stimulating teacher, and contributed to the literature many valuable studies, the most outstanding of which were concerned with the comparative anatomy of the tonsils and with injuries and diseases of the nose and accessory sinuses. He had wide interests outside Medicine, being particularly devoted to exploration and natural history. He was a Fellow of the Royal Geographical Society and of the Zoological Society. He was recognized as an authority on bats, and had carried out an extensive investigation into the problem of basking sharks off the Scottish coast. Hett was also a keen fisherman and a practised shot. He was a kind and courteous chief, a good host, and an entertaining talker on almost any subject. All his patients had a great affection for him because of his charm of manner and gentleness, and there are many who have received kindnesses from him who will mourn his loss. He leaves a son and a daughter.—T.C.

LUDWIG HALBERSTAEDTER, M.D.

Dr. Ludwig Halberstaedter, one of the early pioneers in the field of experimental radiology, died in New York on April 20 at the age of 72. Halberstaedter was born in Beuthen, Silesia, in 1876, and he studied medicine at Breslau University. His research career began with an investigation of the action of x rays on the ovary, the results of which he published in 1905. Bergonnié and Trebondeau published their work on the effects of radiation on the reproductive system later in the same year. In 1907 Halberstaedter went on a research expedition to Batavia and with von Prowaczek published a description of the inclusion bodies in trachoma (Halberstaedter-Prowaczek bodies). On his return to Europe he specialized in dermatology, taking a particular interest in radiation as a therapeutic agent. After the first world war he became director of the radiotherapy section of the Berlin Cancer Institute, and in this capacity he attended as an official delegate the First International Congress of Radiology, which was held in London in 1925. At this time his work was mainly concerned with the treatment of malignant disease by thorium (as a substitute for radium and radon), and his work in this field was outstanding. He was also interested in the treatment of carcinoma of the larynx by a fenestration method which attracted some attention. His experimental work included studies on the radiation of small organisms such as algae and trypanosomes.

As early as 1932 Halberstaedter began preliminary work on the biological action of million-volt x rays, and he also used the cathode-ray tube as a source of radiation. He left Germany in 1933 and took charge of the radiotherapy department of

the Hadassah Hospital in Jerusalem, which developed into the largest radiotherapy centre in that part of the world. He continued his work at the cancer research laboratories of the Hebrew University and published many papers from this department. His interest now lay in irradiation of tissue cultures and other relatively simple biological materials, such as blood corpuscles.

His department was destroyed in 1948, shortly after his colleague and collaborator, Doljanski, lost his life, and these calamities affected his general health. Just when he was about to retire he died suddenly while on a visit to the United States. Altogether he published over a hundred papers in the period from 1903 to 1947. He was fond of teaching, and his students benefited from his wide experience. He found recreation in photography and music, and while he loved serious conversation he had a great sense of fun and a gift of quick repartee which was the delight of his circle of close friends. He is survived by his wife, a daughter, and two sons, one of whom is at St. Mary's Hospital, London.

Dr. FREDERICK GORDON CAWSTON died on March 19 at Durban, where he had practised for many years. He was one of the pioneer workers in Natal on the pathology, prevention, and treatment of bilharzia. There was hardly a river in Natal which he had not patiently and laboriously investigated. Cawston was born in Kent, and was a student at Caius College, Cambridge, and St. Thomas's Hospital. He graduated M.B., B.Ch. in 1910, proceeding M.D. in 1917. He settled in South Africa at the age of 26, and was a resident at Grey's Hospital, Pietermaritzburg, subsequently practising in Greytown, in Krugersdorp, where he was medical officer of health, and in Durban. During the first world war he was a captain in the S.A.M.C. Apart from his scientific work, on which he published many articles, Cawston was a fine organist and piano player, and a very devout Christian. For twenty years he assisted at the services at the Durban gaol, and he gave a great deal of his time to lecturing to various youth organizations and the Y.M.C.A. He was also a member of the Juvenile Affairs Board at Durban. When still a young man Cawston lost the sight of one eye following an accident, and he had badly impaired hearing, so that for the rest of his life he fought—and fought bravely and cheerfully—an uphill fight against these handicaps, which never checked his enthusiasm for research. He leaves a widow, who was founder, and is still president, of the Natal Bantu Blind Society.

Dr. DUNCAN MATHESON MACKAY died at Campbeltown, Argyllshire, on April 12 at the age of 79. He was born in Hull, and graduated M.B., C.M. at Edinburgh University in 1895, proceeding M.D. in 1903. He had also studied at the Middlesex Hospital, and later in Vienna and Berlin. Returning to Hull, he specialized in diseases of the eye, ear, nose, and throat, but subsequently restricted his work to ophthalmology. He was on the honorary staff of Hull Royal Infirmary from 1909 to 1929, and in the absence of one of his colleagues he was recalled to full and arduous duty from 1939 to 1945. With his customary fortitude he went on with his work in the centre of the city of Hull undeterred by enemy air attack, and he had to endure the loss of his only son in the North African campaign and the complete destruction of his home, equipment, and personal property. Dr. Mackay went back to Scotland in 1945, and he continued until recently to practise ophthalmology for the benefit of those for whom the journey to Glasgow might be difficult or inconvenient. He was a devout Presbyterian, taking a deep and generous interest in the affairs of his church. His considerable influence among his colleagues in Hull derived from their respect for his loyalty and high principles. Dr. Mackay was elected chairman of the East Yorkshire Division of the B.M.A. in 1927-8, and was president of the East Yorkshire and North Lincolnshire Branch in 1931-2. Subsequently, until he left the district, he was elected as often as he was eligible to the Branch Council, where his sincerity and honesty were of special value in the consideration of ethical and other problems. Assiduous in his attendance at all medical meetings, Dr. Mackay took an active interest in the purchase of permanent premises by the Hull Medical Society to serve as a centre of medical life in the district and as a regular meeting-place for the discussion of professional matters. He represented the B.M.A. on the Council of Hull University College, and instituted the fund from which a B.M.A. prize is offered to medical students of that college. As local charities secretary of the Association and local secretary of other medical charities and benevolent associations he set a fine example. These engagements in addition to his busy professional life left little time for his literary.

historical, and antiquarian interests. His work for the B.M.A. is permanently commemorated by the gold and enamel badge of the Association which he presented and which is part of the official insignia of the president of the East Yorkshire Branch. Dr. Mackay regularly attended ophthalmic meetings and congresses, particularly those of the North of England Ophthalmological Society, of which he was president in 1933. If he had any ambition it was for a lifetime of service to humanity, and this he can truly be said to have achieved. He will be especially remembered for his modest demeanour, for the courtesy he extended to all, and for his encouragement of younger men. —D. S. S.

Dr. CHRISTOPHER THACKRAY PARSONS, of Havant, Hants, died suddenly as a result of an accident at Cheltenham at the age of 78 on April 22. As a student he won a scholarship at St. Mary's Hospital and qualified L.S.A. in 1892. After holding a number of resident appointments he graduated M.B. in 1894, with honours in physiology and materia medica, and proceeded M.D. in 1895. Early in 1898 Dr. Parsons served in Bombay on special plague duty and on his return took up general practice for a few months. Later in the same year, however, he was appointed medical superintendent of Fulham Infirmary, where he remained until his retirement in January, 1934. The infirmary had by then been taken over by the London County Council and renamed Fulham Hospital. Dr. Parsons was highly esteemed by all his staff, who came to regard him with real affection. During the 1914-18 war he served in the R.A.M.C. with the rank of lieutenant-colonel and was in command of the Fulham Military Hospital; later he commanded a field hospital in Mesopotamia and was awarded the O.B.E. He was honorary secretary of the Infirmary Medical Superintendents' Society in 1908 and 1909 and president in 1912 and 1913. He was examiner in medicine to the General Nursing Council from 1934 to 1945 and the author of several reports on Poor Law relief and on workhouses and similar institutions. Dr. Parsons became a freeman of the Worshipful Society of Apothecaries, by redemption, in 1907, and was Master for a year from August, 1946. He was very proud of this honour and took the greatest interest in the traditional ceremonies which take place in the historic hall of this medical guild. Parsons was a man of small but dignified stature, of original thought always fearlessly expressed, kindly, and with an almost puckish sense of humour. He was endowed with a philosophical mind and unquenchable optimism. Widely travelled, he had a working knowledge of more than one Continental language, was well versed in the classics, and was informed on archaeology and painting. In addition to these accomplishments he was a man of affairs and a most able chairman. He was perhaps at his best as an after-dinner speaker, when his colourful phraseology and apt quotations were listened to with careful attention by all who had the privilege to hear him. He will be missed by many, and the sympathy of his friends will go out to his widow.

A memorial service for the late Dr. A. E. Barclay has been arranged by the British Institute of Radiology at St. Peter's Church, Vere Street, London, W.1, on Friday, May 20, at 11 a.m. Members of the institute, of other radiological bodies, and all who desire to do so are invited to attend. It was Dr. Barclay's wish that mourning should not be worn.

Medico-Legal

NEGLIGENCE BY A SURGEON

Loss of a Little Finger

Mr. Justice Pritchard in the King's Bench Division on April 11 heard a case in which a 7-year-old girl, Jennifer Leggett, brought an action against Mr. Kenneth Aird Ross.

At the age of 18 months the child sustained a burn on the right little finger which left a scar on the proximal phalanx and part of the middle phalanx. It seemed likely to produce a contracture, and on Dec. 17, 1946, Mr. Ross operated at the Hospital for Sick Children, Great Ormond Street. At some time after that date the finger became gangrenous, and finally the distal phalanx and part of the middle phalanx had to be amputated on March 14, 1947. The child, through her father, took action to recover damages in respect of the loss of part of the finger.

Judgment

In his summing up Mr. Justice Pritchard said that negligence was alleged on six points: (1) that Mr. Ross failed to stop the bleeding before sewing up the operation wound; (2) that he sewed it up too tightly; and (3) that he failed to arrange for a sling to be worn by the infant after the operation. In his view there was no substance in these three allegations. He went on to consider the allegations (4) that after the operation Mr. Ross bandaged the finger too tightly; (5) that on Dec. 23 he saw the finger, which was then swollen and painful, and took no steps to remedy the excessive tightness of the bandage or of the stitches; and (6) that on that same day he sent the infant away until Dec. 31, when her condition was such that he should have examined her at frequent intervals during that week.

After reviewing the conflict of evidence on a number of points the judge found the following facts. The finger was bandaged too tightly; the strapping was applied not merely to keep the gauze dressing in place but tightly enough to act as a splint. On Dec. 23 the bandage was cut open to reveal the site of operation, but it was not cut right up to the top of the finger so as to allow examination of the proximal phalanx. On Dec. 31 the finger showed dry gangrene. Since the child had pain from Dec. 17 to Dec. 23, 1946, and had no pain thereafter, the gangrene must have set in between the date of operation, Dec. 17, and Dec. 23.

There was some dispute between Dr. Courtenay Bell and Mr. Ralph Marnham for the plaintiff and Mr. Denis Browne, Mr. Dickson Wright, and Mr. Joseph Fathi for the defendants. It was suggested by the defendants that the bandage could not have caused the dry gangrene and that it might have been due to an arterial spasm in one of the small arteries of the finger. The judge preferred the evidence of Mr. Marnham and Dr. Courtenay Bell, and held that the gangrene was caused by a tight bandage. In putting that bandage on as he did, Mr. Ross was negligent, and on Dec. 23 his examination of the girl was not thorough and was a negligent examination. Mr. Justice Pritchard went on to say:

"Nobody likes saying of a surgeon that he has been negligent. I am quite sure that this case has been a matter of great sorrow and great anxiety to Mr. Ross. I hope that he will find at any rate some comfort in this expression of my view, that there are very few professional men—and I do not exclude lawyers when I say that—who have not at some time or other during the course of the practice of their profession been negligent. It happens I am sure many, many times. It does not always happen that an act of negligence committed in the bustle of a busy day results in an unfortunate chain of circumstances such as occurred in this case. I hope that Mr. Ross will go away from this Court not feeling that he is an isolated person because I have found that he is negligent, and imagine that I think he is unlike other people, because he is not. I hope he will go away, on the contrary, realizing what I really do think, which is that his negligence on these two particular days was something which might have been done by any surgeon without the unfortunate results which did occur in this case, and he has been unfortunate because those unfortunate results did occur."

He assessed the damages at £175, and gave judgment also for £8 14s. 11d. for the father, whose damages were not disputed. Mr. Felix Denny, instructed by Messrs. Milles Day and Co., appeared on behalf of the plaintiffs. Mr. Cecil R. Havers, K.C., and Mr. E. Garth Moore, instructed by Messrs. Hempsons, appeared for the defendants on behalf of the Medical Defence Union.

The International Hospital Federation is holding a congress in Holland on May 30-June 4. The Minister of Health does not consider that the expenses of members and officers of boards and committees attending the congress should be met from Exchequer funds, but he would have no objection to appropriate officers being granted special leave with pay to attend. Any regional board or board of governors that wishes to join the International Hospital Federation may pay the subscription from their Exchequer funds. Any association of boards or of management committees which may be formed would also be able to join the Federation, but individual hospital management committees should not join or subscribe from Exchequer funds. Details of the activities of the Federation and of the congress can be obtained from Captain J. E. Stone, honorary secretary and treasurer, King Edward's Hospital Fund for London 10, Old Jewry, London, E.C.2.

Medical Notes in Parliament

NURSES BILL

Major E. L. O. Hood, and Captain G. D. Powell, R.A.M.C., have been mentioned in dispatches in recognition of gallant and distinguished services in Malaya during the period July 1, 1948, to Dec. 31, 1948.

Lord LLEWELIN welcomed the Bill. He said that previously the register of nurses had been published annually at a cost to the General Nursing Council of about £6,000 a year. He suggested that it should be obligatory to publish this register every five years, a year before the election to the Council took place. He inquired whether the Minister intended to appoint any doctors to the General Nursing Council. It was important that the liaison between doctors and nurses should be complete and that doctors should be able to give advice to the Council and have a say in training. The Working Party put the wastage of student nurses who did not finish the course at 35% in the old voluntary hospitals and 43% in the old municipal hospitals. They would retain more of these student nurses if imagination were shown in their training in hospitals and there was less drudgery. He was glad that mental nurses were to be given their own statutory committee and a place on the General Nursing Council. He suggested that the replacement of out-of-date mental institutions should receive a better place in the Government's programme of capital expenditure. The Working Party estimated that, while the percentage of the population which was mad was now 2.1, it might well increase to 4.1 over the next fifty years.

Medical Views

Lord AMULREE also welcomed the Bill. He said it seemed that medical practitioners were not represented on the General Nursing Council. There was a provision that two teachers should be appointed by the Ministry of Health. These teachers might be doctors but need not be. It would greatly strengthen the Council if there were medical representation. There still was a deficit of 50,000 nurses, although there were now 51,000 student nurses compared with 42,000 before the war. He was not sure whether the country could afford to take a greater number of well-trained and well-educated young women to care for the sick. The Council might give attention to the position of young girls who had a vocation for taking care of the sick but were not good at passing examinations. It was not necessary for all the junior nurses to know as much as the doctors did. It might be useful if there was a linking of management committees and boards of governors on the question of training.

Lord MORAN said the crux of the Bill was in the clauses which for the first time separated funds for the training of nurses from the general hospital budget. The nurses were thereby given self-government so far as their training was concerned. In the past hospitals had too often treated the nurse as a pair of hands. What the nurse did was governed not by her training but by the need of the hospital for cheap labour. Every nurse and doctor thought that the Bill was a milestone in the history of the training of nurses. He congratulated the Minister of Health in doing what he himself had impatiently awaited for forty years. Almost equally important was the provision in the Bill for bringing the standard of efficiency of the smaller hospitals up to the level of the best. Everyone would welcome the bridge between the teaching hospitals and the smaller hospitals in the standing nurse-training committees which were not under the regional hospital boards. If the nurses were in a majority on these committees everyone would welcome their establishment and the financial powers given to them.

When they came to the other executive function, that of examining, the position was different. In 1919 a central State examination for nurses had been established which had done much to raise minimum standards everywhere. Under the Bill there would be no national minimum standard, and he feared there might be a lowering of the standard by regional committees under the pressure of local opinion. The more they were driven to shifts and expedients for meeting the shortage of nurses the more necessary it was to preserve somehow the standards they had known in the past. That was why he was concerned that the teaching hospitals were put into the regional machinery for the purpose of training nurses. This was the first departure from the principle Mr. Bevan had laid down in the Health Service Act that teaching hospitals should be kept outside the regions. The teaching hospitals in the past spent ten times more money in training nurses than did the other hospitals. In the teaching hospitals was the "growing edge" of nursing, and he looked with misgiving on the possibility that that edge would be blunted by putting these hospitals under the regions.

Lord CROOK feared that the experiments which the General Nursing Council would authorise might cause delay in making decisions on general principles. In the next few years the field of recruitment would be more restricted. The number of women available for all kinds of employment in this country would drop by 300,000 in the next four years. The House was bound to ask that decisions on the general staffing problems of the hospitals should come from the Government within the next twelve months. He was surprised that the Bill omitted any suggestion of an annual report from the General Nursing Council.

Independent Financing

Lord WEBB-JOHNSON said he had long pressed for the independent financing of the training of nurses, and he had urged that the status of the nurse in training should be equal to that of an undergraduate in a university. He had had the privilege of planning a nurses college given by Colonel John Astor, which provided in a London hospital a college equal to any in the older universities. He was disappointed that the Minister of Health had selected the General Nursing Council as the body for general control of the funds for bringing about this improvement. He thought that something comparable to the University Grants Committee would be more suitable. Clause 2 of the Bill made it inevitable that the nurse-training committees in each area would be largely under the control of the regional boards. He agreed with Lord Moran that if teaching hospitals were brought under the control of such a committee and of the regional board it would be a matter of great anxiety. He hoped that Clause 5 would provide for educa-

tional grants to hospitals not vested in the Minister. He trusted that the Government would consider accepting on Clause 1 an amendment empowering the General Nursing Council to recognize postgraduate courses and to register extra qualifications.

Lord SHEPHERD said that, although publication of the nursing register cost £6,000 a year, only 200 copies were published, of which only 140 were sold. The policy of the Government to relieve nurses of all work not requiring nursing skill had been announced in 1945 and in notes recently issued for the guidance of hospital management committees. Since June, 1947 domestic employees in hospital had increased from 117,000 to 123,000. The Government intended that grants should be made to the General Nursing Council and through that Council to the training committees to cover the cost of training. The expenditure of hospital management committees in relation to training within the hospitals would also be chargeable to the Government. A Bill for Scotland would be introduced later. In making appointments by the Minister to the General Nursing Council or to the standing nurses training committees there would be prior consultation with organizations representing the medical and other professions. In the past medical men had found their way on to these committees, and under the new dispensation there would be no change. The Minister had for many years included both medical representatives and hospital administrators among his nominees to the General Nursing Council. There was no reason to suppose that any change in this practice was likely. It would be open to regional hospital boards or boards of governors of teaching hospitals to include medical representatives among members appointed by them to the standing nurse-training committees. The constitution of nurse-training committees would be settled by Order.

There was no reason to think that disclaimed hospitals would be prejudiced, and Lord Moran need not fear that the standard of training would be lowered by regional examinations. In the National Health Service Act teaching hospitals were dealt with separately because of their unique position in the teaching of medicine. The same analogy could not be drawn with reference to the training of nurses, of whom only a small proportion were trained in teaching hospitals. The Bill did not provide that the General Nursing Council should publish a report to the Minister, but the matter was being considered, and something more might be said about it before the committee stage.

The Bill was then read a second time.

Fitness of German Generals

The Bishop of CHICHESTER on May 5 in the House of Lords called attention to the cases of Field-Marshal Von Rundstedt, General Strauss, and Field-Marshal Von Manstein. He asked whether these men were fit to stand trial. The Lord Chancellor, Lord JOWITT, said that since he had stated last November that the duty of the British Government was to put these three men on trial reports had reached him indicating that two were not fit to stand trial. Even these reports were not unanimous, and he got the doctors concerned to see him, along with the Attorney General and Professor Sir Henry Cohen. Having heard several of the doctors, they came to the conclusion that the health of Von Rundstedt and of Strauss was not such as to justify the ordeal of a trial which would last six to eight weeks. Everyone agreed that Von Manstein was perfectly fit to stand his trial. Von Manstein was accused of breaches of the usages of war, with the murder of vast numbers of people.

MILK BILL

On April 29 the Milk (Special Designations) Bill passed through the Report Stage in the House of Commons after minor amendments had been moved on the motion of Dr. SUMMERSKILL. The Third Reading debate followed immediately.

Dr. Summerskill said that the Bill would assure consumers of a safe milk supply and the producer would know that the milk would be guarded during all stages of distribution. The Bill was a charter to safeguard young lives from the effects of bovine tuberculosis and to safeguard the community from the risk of milk-borne disease.

Captain CROOKSHANK said the real remedy was to clean up the herds. Until that happy result could be obtained the Bill would certainly serve its purpose.

Mr. SOMERVILLE HASTINGS was astounded that the country had taken so little interest in the Bill. When the Bill came into operation, presumably on Oct. 1, it would become illegal for the accredited producer to mix milk from two or three herds before bottling. That would be a real advance. If milk from more than one herd was mixed the distribution of possible infection was widened and the difficulty of tracing that infection was increased. The term "accredited" would go in October, 1954, and in one area after another, as pasteurizing plants became

B.D.H. CONTRIBUTIONS TO VITAMIN RESEARCH

The British Drug Houses Ltd. have played a leading part in making vitamin products available for use in medical practice. Vitamin A manufacture was an early activity of the B.D.H. and the Carr-Price estimation was evolved in the B.D.H. Laboratories. Calciferol (vitamin D₂) was made available for the first time in Great Britain by the B.D.H. under the name of Radiostol. The vitamin products issued by the B.D.H. include all those of established value in prophylaxis and treatment.

Literature is available on all B.D.H. Vitamin Products and will be forwarded on request.

Preoperative Management of Umbilical Hernia

This male child, age 2½, was presented for treatment because of constipation and abdominal discomfort. Examination revealed an umbilical hernia. Surgery delayed for one year. The Spencer shown (right) was prescribed as adjunct to preoperative treatment to control the hernia and support abdominal organs in position to improve function.

In a Spencer, abdominal support is from below, upward and backward and is properly correlated with back support. Made of non-elastic material it will not yield or slip under strain. Because the Support was individually designed for this child, "it stays in place," is comfortable and safe. Thus patient co-operation is assured. Each Spencer Support is individually designed, cut and made for each patient.

Thousands of doctors prescribe individually designed Spencer Supports for back derangements; following spinal, abdominal or breast operations; displaced internal organs; movable kidney; maternity and following childbirth; certain hernia cases; and other disabilities.

POWER IN ACTION

Where the urgent treatment of an anaemia calls for powerful action, the physician can rely on 'Folvite' (Folic Acid, Lederle) as a potent haematinic.

'Folvite' rapidly restores normal red cell development and maturation—a fundamental factor in the successful treatment of the macrocytic anaemias.

Issued as a parenteral solution of 15 mgm./cc., in tablets of 5 mgm. and as an elixir containing 5 mgm. in each teaspoonful (4 cc.).

'Folvite' Registered Trade Mark.

available, an order would be issued that only designated milk might be sold. But even pasteurized milk was not safe if put into churns and transferred to another bottling plant. He regretted that for the time being this practice was permitted under the terms of the Bill. If it was shown that pasteurized milk could be a source of danger, the whole idea of pasteurization might be discredited. Dr. Summerskill had said during the Committee Stage that she proposed to issue a regulation that after 1954 all milk must be bottled on the spot immediately after being pasteurized. Mr. Hastings regretted that this was not stated in the Bill.

Dr. BROUGHTON felt sure the Bill would help to eradicate bovine tuberculosis. Dr. HADEN GUEST believed the Bill would prove a landmark in the health of the country and especially in the health of the children.

The Bill was then read a third time and passed. It had already passed the House of Lords.

Irish Qualifications

By the Ireland Bill, introduced by Mr. ATTLEE on May 3, it is proposed that, "notwithstanding that the Republic of Ireland is not part of His Majesty's dominions, the Republic of Ireland is not a foreign country for the purposes of any law in force in any part of the United Kingdom or in any colony, protectorate, or United Kingdom trust territory." This is interpreted in Whitehall as implying that Southern Irish medical qualifications will continue to be valid in the United Kingdom.

Alien Doctors

On May 5 Mr. WILLIAM WELLS asked how many applications had been made for registration under Section 3 of the Medical Practitioners and Pharmacists Act, 1947; how many such applications were pending; for how long they had been pending; and when they would be decided.

Mr. BEVAN replied that in all there had been 174 medical applications, of which 39, made at varying dates during the last year, were still pending. The decision on nine of these had been deferred for the time being in the applicants' own interest. These applicants, being abroad, could not be registered unless resident in the U.K. Further information was awaited from 10. An early decision was expected on 3. One application was received a few days ago. The remaining 16 involved legal questions of some difficulty which the G.M.C. was endeavouring to resolve as speedily as possible.

Mr. WELLS asserted that one application had been delayed for a year. Mr. BEVAN remarked that as he did not know this case he could not say that the delay was unreasonable.

Homeopathy

On May 5 Mr. SKINNARD asked whether Mr. Bevan would arrange that lists of homeopathic medical practitioners, similar to publicly exhibited lists of practitioners in other specialized fields of medical service, were provided for the information of persons desirous of homeopathic treatment.

Mr. BEVAN refused to do this. He said it would not be in the public interest to seek to distinguish different forms of therapy practised by doctors providing general medical services. Various forms of treatment often differed with the doctors who gave them. It was undesirable to distinguish between one form of treatment and another. Homeopathic treatment could be given by registered medical practitioners. There was no reason why it should be distinguished from other forms of treatment.

Colonel STODDART-SCOTT asked Mr. Bevan to assure the House that he would add no names to the list except those of practitioners who had adequate medical education and appropriate medical qualifications.

Mr. BEVAN said no one was allowed to practise who was not on the *Medical Register*. It was assumed that those registered had an adequate medical education.

Dr. SEGAL said it was felt to be unethical for any doctor to advertise himself as a practitioner in a particular form of treatment.

Mr. SKINNARD said he did not ask that a doctor should advertise himself, but that information should be given to patients under the National Health Service.

Mr. BEVAN said the action suggested by Mr. Skinnard would tend to advertise certain forms of treatment.

Milk in Scotland.—Mr. WOODBURN stated on April 26 that there were 100 pasteurizing or heat-treatment plants in Scotland. The milk from these was tested fortnightly and the results generally were satisfactory. Of the milk sold off Scottish farms, some 70% was from tuberculin-tested herds. Milk as sold to the public comprised approximately 10% sold as "T.T." 70% pasteurized or heat treated, and 20% sold as ordinary non-pasteurized milk.

No. 16

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 23.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland. *Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.*
A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

|| Includes puerperal fever for England and Wales, Eire, and Northern Ireland.

EPIDEMIOLOGICAL NOTES

Typhoid Fever at Crowthorne

Cases of typhoid fever associated with the outbreak at Crowthorne (May 7, p. 827) have been reported from Camberley, Didcot, and Ramsgate, and the total is now 38. Although the source and mode of infection have not yet been discovered, the evidence so far obtained suggests that the vehicle of infection was distributed only in Crowthorne and over a limited period of time, probably about April 16. The fears at first entertained of there being a very large number of cases may therefore prove to be unwarranted.

Smallpox

No further cases have been reported among passengers from the s.s. *Mooltan*. On May 7 an unvaccinated woman aged 20 was admitted to Liskeard Smallpox Hospital in Cornwall as a suspected case of smallpox. The diagnosis has since been confirmed by laboratory tests. It has not been possible to establish the connexion between this patient, who resided in a small village a few miles from Liskeard, and any of the patients previously reported among the passengers from the *Mooltan*.

Discussion of Table

In *England and Wales* there were increases in the notifications of measles 448 and whooping-cough 279, with a decrease of 86 in the notifications of scarlet fever.

Decreases in the notifications of measles were recorded in Essex 162, Middlesex 153, and Glamorganshire 112; there were increases in Surrey 131 and Kent 117. A small increase in the incidence of whooping-cough was recorded in most areas—for example, Essex 41 and Middlesex 34; the only noteworthy exception to the general trend was a decrease of 37 in London.

The notifications of scarlet fever showed very little change from the preceding week; the largest changes were decreases in Lancashire 33 and Essex 25. There was no variation of any size in the local returns of diphtheria.

No large outbreaks of dysentery were notified during the week. The chief centres of infection were Lancashire, Liverpool C.B. 8; Yorkshire West Riding, Huddersfield C.B. 8; Cumberland, Penrith R.D. 5; Essex, West Ham C.B. 5; and Norfolk, Norwich C.B. 5.

In *Scotland* infectious diseases were more prevalent during the week. There were increases in the notifications of acute primary pneumonia 67, measles 34, cerebrospinal fever 15, scarlet fever 12, and dysentery 10. There was a fall in the incidence of whooping-cough 31. These changes in the trends of infectious diseases were mainly contributed by Glasgow. The rises in the incidence of dysentery were in the cities of Glasgow 6 and Stirling 5. The chief feature of the notifications of diphtheria was an increase of 10 in Glasgow.

In *Eire* increases were recorded in the notifications of measles 20, whooping-cough 70, diarrhoea and enteritis 24, and scarlet fever 22. In Dublin C.B. there were increases in the incidence of measles 107, whooping-cough 62, scarlet fever 18, and diarrhoea and enteritis 17.

In *Northern Ireland* the notifications of measles rose by 15 and the notifications of whooping-cough fell by 23. The incidence of measles declined in Belfast C.B. 17 and County Armagh 17. The decrease in the incidence of whooping-cough was fairly general throughout the country.

Tuberculosis, Cancer, and Maternal Mortality

The provisional death rates per million population for England and Wales during 1948 were as follows:

	Males	Females	Persons
Respiratory tuberculosis	555	335	440
Other tuberculosis	72	62	67
Cancer	1,965	1,761	1,858

The maternal mortality per 1,000 total live and still births in England and Wales in 1948 was:

Post-abortion infection	0.11
Abortion without mention of septic conditions	0.05
Infection during childbirth and the puerperium	0.13
Other maternal causes	0.73
Total	1.02

Excluding abortion 685 mothers died in childbirth in 1948, and deaths due to abortion numbered 123.

Week Ending April 30

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 785, whooping-cough 2,905, diphtheria 98, measles 11,436, acute pneumonia 453, cerebrospinal fever 32, dysentery 38, acute poliomyelitis 14, paratyphoid 1, and typhoid 6. Deaths from influenza in the great towns numbered 39.

Medical News

Research into Home Analgesia

The Medical Research Council has set up a committee to carry out research into analgesia suitable for use by midwives on a recommendation in the Report of the Working Party on Midwives. The chairman is Sir William Gilliatt, P.R.C.O.G., and the secretary Mr. G. S. W. Organe, anaesthetist to Westminster Hospital, who is also secretary of the Council's Anaesthetics Committee. The other members are: Dr. Josephine Barnes, Dr. Albertine Winner, Professor R. R. Macintosh, Dr. E. A. Pask, Professor A. D. Macdonald, and Dr. F. H. K. Green. The committee's terms of reference will include the study, if thought desirable, of modified methods of administering existing analgesic agents as well as the initiation of further research for new agents. Investigations are likely to take a considerable time. Before a final decision can be reached on any new methods by which midwives could safely administer analgesics without medical supervision, extensive clinical trials will probably be necessary. These may have to be conducted at home confinements in charge of midwives. At present the Central Midwives Board—upon whom responsibility rests for approving drugs and apparatus for the administration of analgesics by midwives—has approved the gas-and-air method for midwives specially trained in its use. The Board has been advised by the Royal College of Obstetricians and Gynaecologists, and so far five different types of gas-and-air machines have been approved.

Award of Mickle Fellowship for Dr. Avery Jones

Dr. Francis Avery Jones has been awarded the William Mickle Fellowship by the University of London for 1948-9. It is of the value of approximately £250, and is offered annually to a man or woman resident in London and a graduate of the University who in the opinion of the Senate has done most to advance medical or science within the preceding five years and has therein shown conspicuous merit. Dr. Avery Jones is Physician and Deputy Medical Director at the Central Middlesex County Hospital. He graduated in 1934, taking the M.R.C.P. and proceeding M.D. two years later; he was elected F.R.C.P. in 1946. His Goulstonian Lectures on "Haematemesis and Melaena" were published in this *Journal* on Sept. 20 and 27, 1947.

American National Health Council

At the 29th Annual Meeting of the American National Health Council held recently Mr. Philip R. Mather was elected president, Dr. Ernest L. Stebbings vice-president, Dr. Haven Emerson treasurer, Dr. Franklin M. Foote assistant treasurer, and Dr. James E. Perkins secretary. Four additional organizations were elected to membership in the Council, which consists of leading national health agencies, voluntary and governmental. Those elected were: the American Medical Association and the National Infantile Paralysis Foundation, both elected to active membership; the American Physical Therapy Association and the National Multiple Sclerosis Society, associate members.

Index to National Formulary

The Northern Ireland General Health Services Board has issued to general practitioners in the Northern Ireland Health Service an index to the *National Formulary*. The drugs are listed under sub-headings as "Formulae Containing Penicillin," "Used in Treatment of Coughs," and "Analgesics, Anodynes, Hypnotics, and Sedatives."

Peckham Health Centre Bulletin

Peckham Health Centre has issued the first number of a monthly bulletin entitled *Peckham*. It is attractively produced and illustrated and includes short articles on the health centre's work and history. The subscription for twelve issues is 7s. 6d., post free. It may be obtained from the Editor, *Peckham*, 8F, Hyde Park Mansions, London, N.W.1.

Argentine Society of Pathology

Professor Humberto R. Rugiero has been elected President of the Argentine Society of Pathology.

Diamorphine Linctuses: Correction

The Home Office has drawn the attention of the Ministry of Health to an error in the information it has recently issued (*Journal* April 23, p. 733, and April 30, p. 787) about the dispensing of linct. diamorphinae *N.W.F.* The only prescriptions for Dangerous Drugs which may be ordered by title are those named in the *B.P.*, the *B.P.A.* or the *Drug Tariff*. All other prescriptions not written out in full cannot be dispensed but must be returned to the doctor for amplification. Since the *N.W.F.* is no longer a recognized formulary, a chemist would be acting illegally in dispensing linct. diamorph. *B.P.* when linct. diamorph. *N.W.F.*, which is no longer included in the *Drug Tariff*, is prescribed.

Czechoslovak Award

The President of the Czechoslovak Republic has conferred the decoration of Chevalier of the Order of the White Lion upon Dr Frederick Himmelweit in recognition of services rendered during the war.

COMING EVENTS**Bicentenary of the Birth of Edward Jenner**

The Royal College of Physicians of London and the Royal College of Surgeons of England are commemorating the 200th anniversary of the birth of Edward Jenner on May 17. During the afternoon at the Royal College of Surgeons (Lincoln's Inn Fields, London, W.C.), Sir Edward Mellanby, F.R.S., will deliver a commemorative lecture entitled "Jenner and his Impact on Medical Science." In the evening there will be a reception at the Royal College of Physicians (Pall Mall East, London, S.W.). Admission to both these functions is by invitation only.

Medical Golf

The Annual Competition of the Manchester and District Medical Golfers' Association will be held on the course at Mere, Cheshire, on May 25. The Challenge Cup will be competed for by medal play under nandicap. The Walter Gold Medal will be held for one year by the member returning the best gross score; the Walter Silver Medal will be held for one year by the member returning the best gross score from among those with handicaps of ten and upwards. Two prizes will also be presented (1) for the best net score for holes 1-9, and (2) for the best net score for holes 10-18. The annual subscription is 7s. 6d., and comprises the entrance fee of the Annual Competition. New members are required. Any medical man is eligible for membership provided he is a member of a recognized golf club within the area. Particulars may be obtained from the hon. secretaries, Manchester and District Medical Golfers' Association, c/o British Medical Association, 33, Cross Street, Manchester, 2.

Association of Surgeons of Great Britain and Ireland

The annual meeting of the Association of Surgeons of Great Britain and Ireland will be held at University College (Physics Theatre), Earlsfort Terrace, Dublin, on May 26, 27, and 28. The programme is as follows: May 26, 9.30 a.m., business meeting, 10 a.m., discussion on "Surgical Ritual," to be opened by Sir Hugh Cairns, Sir Reginald Watson-Jones, Mr Julian Taylor, Mr F. Gill, and Mr D. M. Douglas, 2.15 p.m., operating sessions or demonstration of cases at various Dublin hospitals, 4 p.m., at Trinity College, lecture by Professor Geoffrey Jefferson, F.R.S., "Descartes and the Localization of the Soul," 5 p.m. to 7 p.m., reception at Trinity College by invitation of the Provost, 7.45 p.m., annual dinner at Gresham Hotel. May 27, 9.30 a.m., discussion on "The Use and Abuse of Streptomycin (excluding Pulmonary and General Tuberculosis)," to be opened by Sir Alexander Fleming, F.R.S., Mr E. W. Riches and Mr A. Dickson Wright, 11.45 a.m., alternative meetings at (a) University College, discussion on "Resection and Reconstruction of the Trachea," to be opened by Mr C. G. Rob and Mr R. H. Belsey, and at (b) Royal College of Surgeons in Ireland, short paper by Mr Geoffrey L. Keves, "Tumours of the Thymus Gland," 2.15 p.m., operating sessions or demonstrations of cases at various Dublin hospitals, 5 p.m. to 7 p.m., reception by the Minister of Health. May 28, 9.30 a.m., short paper by Professor J. Adams-Ray (Stockholm), "Hypertonus in Venous Capillaries," followed by discussion on "Treatment of Injuries to Peripheral Nerves," to be opened by Professor J. Z. Young, F.R.S. ("The Process of Nerve Repair"), Mr H. J. Seddon ("Indications for Exploration, Suture, and Grafting"), Sir James Learmonth ("Neurovascular Injuries"), Mr R. B. Zachary ("Results of Nerve Repair"), and Miss Ruth Bowden ("Certain Factors Influencing Recovery"). Full particulars of the meeting may be obtained from the honorary secretary of the association (Mr H. W. S. Wright, F.R.C.S.) at 45, Lincoln's Inn Fields, London W.C.2.

St Cyres Lecture

Professor K. D. Wilkinson will deliver the St Cyres Lecture on "Withering" at the Royal Society of Medicine (Barnes Hall), 1, Wimpole Street, London, W., and not at the Institute of Cardiology as announced in the *Journal* of April 30, (p. 784), on Wednesday, June 15, at 5 p.m.

Simpson-Smith Memorial Lecture

The second Alexander Simpson Smith Memorial Lecture will be delivered by Mr R. C. Brock at the Medical Society of London, 11, Chandos Street, W., on Wednesday, June 15, at 8.30 p.m., with Lieutenant-General Neil Canthie, Director-General, Army Medical Services, in the chair. His subject is "The Surgical Treatment of Congenital Pulmonary Stenosis." Admission is by ticket only. Early application should be made to the Dean, West London Hospital Medical School 1 and 3, Wolverton Gardens, Hammersmith W.6.

Lectures on Pituitary Hormones

Professor Miriam E. Simpson, of Berkeley University, California, will give a series of lectures at the Hôpital Laennec, Paris, on June 27-July 9. The lectures will be in English. The fee for the course is 3,000 francs. Particulars may be obtained from Dr Loubble, 20, Rue Marbeau, Paris, 16. Registrations cannot be accepted after June 20.

Summer School in Austria

The British Social Hygiene Council will hold a summer school on "The Family and the Nation" at Pertisau, in the Austrian Tyrol, from Aug. 17 to Sept. 1. Subjects to be discussed include nutrition, human heredity, the welfare of old people, and juvenile delinquency. The school is intended primarily for magistrates, almoners, nurses and teachers. The inclusive cost is about £34. Information may be obtained from the B.S.H.C., Tavistock House North, Tavistock Square, London W.C.1.

SOCIETIES AND LECTURES**Monday**

BIRMINGHAM UNIVERSITY—At Anatomy Theatre, Medical School, Birmingham, May 16, 4 p.m., "The Excretion of Water by the Kidney, with Special Reference to its Neurohypophyseal Control," William Withering Lecture by Professor E. B. Verney, F.R.S.
EDINBURGH UNIVERSITY—At Physiology Lecture Theatre, University New Buildings, Teviot Place, Edinburgh, May 16, 5 p.m., "Maya and Ica Medicine" by Dr Douglas Guthrie.
LONDON UNIVERSITY—At King's College, Strand, W.C. May 16, 5.30 p.m., "Venous Return in Health and Disease," by Professor K. I. Gollwitzer-Meier (Hamburg).
LONDON UNIVERSITY COLLEGE—At Physiology Theatre, Gower Street, W.C., May 16, 4.45 p.m., "Selective Toxicity with Special Reference to Chemotherapy" by Professor Adrian Albert.

Tuesday

BIRMINGHAM UNIVERSITY—At Anatomy Theatre, Medical School, Birmingham, May 17, 4 p.m., "The Excretion of Water by the Kidney, with Special Reference to its Neurohypophyseal Control," William Withering Lecture by Professor E. B. Verney, F.R.S.
EDINBURGH POSTGRADUATE BOARD FOR MEDICINE—At Anatomy Lecture Theatre, University New Buildings, May 17, 5 p.m., "Viruses and Acute Pulmonary Disease in Man," by Professor C. H. Stuart-Harris.
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—May 17, 5 p.m., "Sex Hormones in Dermatology" by Dr D. I. Williams.
INSTITUTE OF UROLOGY—At St Paul's Hospital, Endell Street, London, W.C., May 17, 11 a.m., "Modern Interpretation of Serological Reactions" by Dr R. Thomson.
LONDON UNIVERSITY—At London School of Economics and Political Science, Houghton Street, Aldwych, W.C., May 17, 5 p.m., "The National Health Service" by Sir James S. Ross.
LONDON UNIVERSITY COLLEGE—At Physiology Theatre, Gower Street, W.C., May 17, 5.15 p.m., "Physiological Properties of Ethyl Alcohol" by Dr M. Grace Eggleston.
ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—May 17, 4 p.m., "Jenner and His Impact on Medical Science" by Sir Edward Mellanby, F.R.S. Lecture to commemorate the bicentenary of the birth of Edward Jenner.
WRIGHT FLEMING INSTITUTE OF MICROBIOLOGY, St Mary's Hospital Medical School, Paddington, W.—May 17, 5 p.m., "Bacterial Antigens" by Dr W. T. J. Morgan, F.R.S.

Wednesday

GLASGOW UNIVERSITY DEPARTMENT OF OPHTHALMOLOGY—May 18, 8 p.m., "The Structure of the Vitreous Humour" by Dr Antoinette Pine.
INSTITUTE OF UROLOGY—At St Paul's Hospital, Endell Street, London, W.C., May 18, 11 a.m., "Cerebrospinal Fluid Tests for Syphilis" by Dr R. Thomson.
LONDON UNIVERSITY—At King's College, Strand, W.C., May 18, 5.30 p.m., "Blood reaction and Blood flow in Muscular Activity" by Professor K. I. Gollwitzer-Meier (Hamburg).
OXFORD UNIVERSITY—At Radcliffe Infirmary, Oxford, May 18, 5 p.m., "Neurological Problems of Childhood" by Dr Franc D. Ingerham (Harvard).
ROYAL SOCIETY OF ARTS, John Adam Street, Adelphi, London, W.C.—May 18, 2.30 p.m., "Scientific Information Services." Aldred Lecture by Sir Alfred Eerton, F.R.S.
ROYAL MICROSCOPICAL SOCIETY—At B.M.A. House, Tavistock Square, London, W.C., May 18, 5.30 p.m., Discussion: "Mechanism of Cell Division" to be opened by Dr A. F. W. Hughes, F.R.M.S.
SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP—At London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C., May 18, meeting of Nutrition Panel (1) 6 p.m., annual general meeting, (2) 6.15 p.m., "Biscuits, Cakes, and other Flour Confectionery" as F. W. S. Butterworth (Introductory) Mr. Full Messrs D. M. Freeland and Bradi; Yudin (Nutritive Value of Confectionery).

Thursday

BIRMINGHAM UNIVERSITY.—At Anatomy Theatre, Medical School, Birmingham, May 19, 4 p.m., "The Problems of Stress Incontinence of Urine in the Female," Ingleby Lecture by Mr. Charles D. Read.

BRITISH ASSOCIATION OF PHYSICAL MEDICINE.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., May 19, 5 p.m., "The Mechanism of Pain," by Dr. Graham Weddell.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, London, W.—May 19, 8.30 p.m., "Medical Radiology. Retrospect and Prospect," Presidential Address by Dr. Hugh Davies; followed by film: "Cineradiography of Joints," by Dr. A. E. Barclay and Mr. H. J. Seddon.

EDINBURGH UNIVERSITY.—At University New Buildings, Teviot Place, Edinburgh, May 19, 5 p.m., "Fat Absorption and Some of Its Problems," Sharpey Schafer Memorial Lecture by Professor H. S. Raper, F.R.S.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., May 19, 11 a.m., "Treatment of Syphilis," by Dr. W. N. Mascall.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Chase Farm Hospital, The Ridgeway, Enfield, May 19, 3 p.m., meeting.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At 26, Portland Place, London, W., May 19, 7.30 p.m., "Tropical Diseases in Brazil," by Professor B. Malamos (Athens). Illustrated by lantern slides.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—May 19, 4.30 p.m., "Neurology," lecture-demonstration by Dr. A. Feiling.

Friday

FACULTY OF RADIOLOGISTS: THERAPY SECTION.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., May 20, 2.15 p.m., "The Value of X-ray Examination in Bronchogenic Cancer," Skinner Lecture by Dr. P. F. Möller (Copenhagen).

APPOINTMENTS

POSTGRADUATE MEDICAL SCHOOL OF LONDON: DEPARTMENT OF ANAESTHETICS.—Senior Lecturer, H. Woodfield-Davies, L.M.S.S.A., D.A., F.F.A.R.C.S.; Lecturers, A. J. W. Beard, M.D., D.A., F. G. Wood-Smith, M.B., B.Chir., D.A.; Assistant Lecturers, Dorothy Spence-Sales, M.B., Ch.B., D.A., Hilda Roberts, M.R.C.S., L.R.C.P., D.A., J. A. Smith, M.B., B.Chir., D.A.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Rosewarne.—On April 12, 1949, at 26, Latchett Road, Woodford, London, E., to Barbara, wife of Dr D. D. Rosewarne, a daughter.
Walton.—On April 29, 1949, at the Queen Elizabeth Hospital, Birmingham, to Cynthia (née Mors), wife of Kenneth Walton, M.B., B.S., a daughter.
Wand.—On May 2, 1949, at Wellhouse Hospital, Barnet, to Betty (née Manders), wife of Dr L. G. R. Wand, a daughter—Penelope Jane.

MARRIAGES

Goldacre-Wight.—On March 20, 1949, at St. Luke's, West Norwood, James A. H. Goldacre, M.R.C.S., L.R.C.P., to Miss Barbara Wight, M.C.S.P., M.E.L.T.
O'Reilly-Gavin.—On April 30, 1949, at St. Edmunds, Bolton, P. O. O'Reilly, M.B., B.Ch., deputy R.S.O., Bury Infirmary, and 42, Bolton Street, Dublin, to Miss Margaret Gavin, Bolton Royal Infirmary.

DEATHS

Ig.—On April 23, 1949, at Royal Sussex County Hospital, Barry Alexander Craig, L.R.C.P.S.I. and L.M., Lieutenant-Colonel R.A.M.C., retired, of Beech Cottage, Burgess Hill, Sussex.
Devas.—On April 23, 1949, Horace Charlton Devas, M.R.C.S., L.R.C.P., Surgeon Captain R.N. retired.
Eccles.—On April 24, 1949, at Driffield, Robert Burton Eccles, M.R.C.S., L.R.C.P.
Gemmell.—On April 20, 1949, Leonard Woodburn Gemmell, M.B., Ch.B., Surgeon Commander R.N., retired.
Hope.—On April 21, 1949, at 5, The Avenue, Knaresborough, Charles William Menclaus Hope O.B.E., F.R.C.S., aged 68.
Kay.—On April 24, 1949, at Leamington Spa, Winifred Julia Kay, M.B., B.S.
McEntire.—On April 25, 1949, in London, following an operation, Samuel Drummond Greer McEntire, L.R.C.P.S.I. and L.M., of Great Baddow, Chelmsford, Essex.
McGregor.—On April 23, 1949, at a Glasgow hospital, George Charles McGregor, M.B., Ch.B., late of Kuala Lumpur, F.M.S.
MacKellar.—On April 21, 1949, at Ash Tree House, Savile Town, Dewsbury, John Donald Matheson MacKellar, M.B., Ch.B.
Nightingale.—On March 30, 1949, at Thurnby, 17, Devonshire Road, St. Annes-on-Sea, Wilfrid Nightingale, M.B., Ch.B.
Parsons.—On April 22, 1949, at Cheltenham, Christopher Thackray Parsons, O.B.E., M.D., of South Leigh Road, Havant, aged 78.
Pateron.—On April 20, 1949, at Liberton Hospital, Edinburgh, Thomas Clarkson Pateron, M.B., Ch.B., aged 69.
Phillips.—On April 25, 1949, at The Priory, Roehampton, Charles Morley Phillips, M.D., formerly of Bristol, aged 80.
Pollock.—On April 22, 1949, Edward Stoute Pollock, M.D., of Hilcot, Rydon Lane, Exeter.
Power.—On April 26, 1949, at 20, Hazelwood Lane, Palmers Green, London, N., Maurice Aloysius Power, M.C., M.B., B.Ch.
Saxby.—On April 19, 1949, at Berkhamsted, Ida B. Saxby, D.Sc., M.R.C.S., L.R.C.P.
Trewby.—On April 17, 1949, Henry William Trewby, M.R.C.S., L.R.C.P., L.D.S. of Hurbourne, Tarrant, Andover, Hants.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Inoculation against Typhoid and Tetanus

Q.—I have recently seen it advocated that children living on a farm should be inoculated against tetanus and typhoid. What dosage would you suggest for the following ages: 8, 6, 5, 4 years, and 6 months? Is it necessary to inoculate against typhoid when the water is pumped up from a specially sunk deep well?

A.—Inoculation against typhoid for children living on farm would seem advisable only if it is known that this disease is endemic in the area and if there is reason to suspect the water supply. A pumped water supply from a deep well should be satisfactory if precautions have been taken to prevent the risk of contamination with sewage. If there is some doubt about the purity of the water, arrangements should be made with the medical officer of health for samples to be tested bacteriologically. Children under 1 year need not be inoculated against typhoid. For all children up to 8 years one-third of the adult dose should be given.

Tetanus is a very rare infection in Britain, and the risk to country children must be small. If, however, protection is desired, it is preferable to give the children two doses of tetanus toxoid at an interval of six weeks or more rather than to give them a dose of tetanus antitoxin whenever they have any accidental wound which might be contaminated with soil containing tetanus spores. A primary course of immunization should be reinforced by a boosting dose one year later. The dose of tetanus toxoid for a child under 1 year should be a quarter of the adult dose—0.25 ml.—and for older children one-third to one-half of an adult dose—0.3 to 0.5 ml.

Thoracoplasty

Q.—Is thoracoplasty now being done in one stage and with the removal of two or three ribs only? What are the indications for this one-stage operation, and are the results as good as those of the more extensive procedure?

A.—The general trend in the technique of thoracoplasty for pulmonary tuberculosis has been towards more selective operations. The old paravertebral thoracoplasty of Sauerbruch and the more extensive operation of Brauer were usually complete in that parts of all the ribs, with the exception of the lowest two or three, were removed. The aim of the modern operation is to produce a selective collapse and relaxation of the affected part of the lung and to make this local collapse as complete as possible. For anatomical reasons truly selective collapse of this sort by plastic operations on the ribs is usually possible only for lesions involving the upper part of the lungs. For these an attempt is made to adapt the size of the operation to the degree of collapse thought to be required to deal effectively with the diseased area; the usual criterion of effectiveness is closure of cavities. The effectiveness of the collapse is often increased in suitable cases by combining the operation on the ribs with some form of apicolysis. Generally, however, the operation must be done in more than one stage, and it is very seldom that, even for high apical cavities, a procedure involving fewer than five ribs is satisfactory. The number of stages required will depend partly on the extent of collapse required to control the disease and partly on the patient's general condition; a severely ill patient will tolerate less at each stage than one in good condition. Since the extent of the procedure should be modified to suit the extent of the disease, one cannot usefully discuss the results of limited as opposed to extensive operations.

Blood-clot and Haemostasis

Q.—Could you explain why clot prevents haemostasis? Why is it that clearing clot out of a bleeding tonsillar fossa or a tooth socket will often stop the bleeding?

A.—To be haemostatically effective, a blood-clot must be firmly and completely attached, forming an impervious seal

that covers a damaged area and extends down to its severed vessels. Clot formation of this sort cannot occur if there is an uninterrupted flow of blood, and normally a period of temporary vasoconstriction following injury provides time for firm coagulation to occur. If, for any reason, this vascular response is incomplete—or, more rarely, if blood coagulation is defective—loose, inefficient clots are produced, from beneath which bleeding continues. Such clots should therefore be regarded as being usually the result rather than the cause of defective haemostasis. Nevertheless, their mechanical removal will often achieve haemostasis, probably by direct stimulation of the cut vessels, with consequent constriction and the formation of a new and firmly attached clot. Removal of loose clots also allows any dressings, styptics, or simple pressure that may be applied to come into direct, and therefore effective, contact with the bleeding vessels.

Subarachnoid Haemorrhage

Q.—Is it reasonable to expect a large quantity of blood in the spinal subarachnoid space and a very small quantity in the cerebral subarachnoid space in a person with subarachnoid haemorrhage who died five days after being found unconscious in the street?

A.—The question does not state the cause of death, or whether the case was one of head injury or of "spontaneous" subarachnoid haemorrhage. But it is a very common post-mortem finding that intracranial subarachnoid haemorrhage has occurred into or has gravitated into the large subarachnoid cisterns about the base of the brain. The admixture of cerebrospinal fluid retards clotting. As the individual survived for five days after being found unconscious, and as there is no information about his posture or condition during that time, the blood may well have drained from the intracranial subarachnoid cisterns, by means of the very adequate communications which exist, into the spinal subarachnoid space.

Absorption of Mercury

Q.—It has recently been reported that the use of teething powders containing mercury may be the cause of pink disease. Is there any likelihood of absorption of mercury by a woman using a contraceptive containing it?

A.—The evidence that pink disease is due to mercury poisoning is very incomplete, and amounts to little more than a suggestion that this may be so. If mercury is a cause, it acts in this way only in those children who have an idiosyncrasy to it. The possibility that mercury is absorbed from a mercury-containing contraceptive is another matter about which there is no certainty. Some consider that there is no danger of mercury absorption; others, that there is a real danger. It is certainly true that the body has a remarkable capacity for absorbing mercury in circumstances in which such absorption would seem unlikely. The risk of absorption would be increased in cases in which the remains of the contraceptive were not removed by douching.

North American Blastomycosis

Q.—I have a patient in whom, after any superficial injury, an ulcer with much scabbing has always formed in the scar. Last December she underwent herniotomy and the scar had almost healed, when a similar reaction took place; the presence of *Blastomyces dermatitidis* was demonstrated microscopically in the scab. I would welcome any information about treatment, particularly with regard to the newer antimicrobials.

A.—Potassium iodide is the sheet-anchor in the therapy of North American blastomycosis. It is administered in graduated dosage, increasing almost to the limit of tolerance and continued beyond the period of apparent clinical recovery. One method is to start with 15 minims (0.9 ml.) daily of a saturated aqueous solution of potassium iodide divided into three 5-minim (0.3-ml.) doses well diluted with water, and increasing by 1 minim (0.06 ml.) daily (not 1 minim per dose daily) until the dosage of 60 minims (3.6 ml.) daily is reached. At this point, or earlier if symptoms of iodism appear, the dosage reverts to the original 15 minims daily and the series is repeated. Treatment should be continued for several weeks or months, as determined by its effects. Sodium iodide intravenously and

ethyl iodide by inhalation may be given alternatively or in conjunction with the orally administered potassium iodide. Patients with blastomycosis frequently show a high degree of allergic sensitivity to the causative fungus, and, in such cases the administration of iodide may cause a severe and even dangerous reaction. It is advisable, therefore, to apply the blastomycin test of dermal sensitivity before instituting treatment and, if necessary, to desensitize the patient by graduated doses of *Blastomyces dermatitidis* vaccine. Iodide treatment should be combined with, or in fact preceded by, specific vaccine therapy, supplemented by surgical and radiotherapeutic measures when indicated, and by general supporting treatment with appropriate diet, vitamins, and rest. The systemic form of the disease requires hospital treatment. The questioner should consult *Clinical Mycology*, by Conant and others (Saunders, 1945), for a detailed account of the treatment.

Blastomycosis (Gilchrist's disease) is indigenous to North America, and reports of the infection from other parts of the world have usually been based on wrong diagnoses. The literature contains only two well-authenticated records of the infection having been contracted in the Old World—one in London in 1925 and the other in France in 1947; both the patients had been engaged in handling materials imported from the United States. Therefore, unless the microscopical diagnosis in the present case has been made by a competent mycologist, it should be confirmed by isolation of *Blastomyces dermatitidis* from the lesions or by serological tests.

Grading of Catheters

Q.—How do the various catheter scales compare, and are they all related to any basic measurement? Would it not be possible to standardize and unify these systems?

A.—The majority of urologists use French catheters. The Charrière scale expresses its measurement in multiples of one-third of a millimetre; thus No. 5 indicates a diameter of $1\frac{2}{3}$ mm. It is true that some of the French catheter-makers have recently adopted the Beniqué scale, in which a No. 10 represents No. 5 Charrière, but the majority of French catheters in this country are marked in the Charrière scale. The English scale is approximately one-half of the French, a No. 10 French being represented by a No. 5 English. It would, of course, be of advantage if English and American manufacturers would adopt the Charrière scale. The American scale is rarely used even by American instrument-makers. Its numbers correspond to two-thirds of the French numbers—that is to say, No. 20 American represents No. 30 French.

Angina of Effort

Q.—A retired doctor aged 74 has the classical symptoms of effort angina, for which the usual remedies, such as nitroglycerin and potassium iodide, have been tried. Any further advice on treatment and climate would be welcomed.

A.—On the whole, patients with angina pectoris are better in warm climates than in cold, but far less so than those with intermittent claudication; in fact, Lewis denied that cold weather had any demonstrable effect on angina, but this, however, is contrary to clinical experience. When conservative measures fail to the extent that the patient is incapacitated by angina, more drastic treatment is indicated. At the present time there are two methods that are perhaps most favoured: (1) administration of thiouracil, and (2) bilateral stellate and upper dorsal sympathectomy. It is doubtful, however, whether either method of treatment should be recommended without the advice of a specialist in cardiology.

(1) Methyl or propyl thiouracil may be given in doses of 0.2 g. thrice daily until improvement is noted, when the dose may be gradually reduced to the minimum that is effective (0.05 to 0.2 g. daily). If there is no improvement within six weeks treatment should be abandoned. Toxic reactions, particularly fever and rash, are rare with propyl thiouracil but less so with methyl thiouracil, and may not be well tolerated by those subject to angina. Agranulocytosis is very uncommon and there is no need for weekly white-cell counts, but the patient should be instructed to report at once in the event of a sore throat, when penicillin should be given immediately and a white-cell count.

withheld. The object of thiouracil treatment is not only to reduce the oxygen requirement and hence the work of the heart, but also to minimize the physiological response to adrenergic substances.

(2) If thiouracil fails, the pain pathways from the heart may be excised. The type of sympathectomy named above appears to reduce the risk of ventricular fibrillation and may improve the efficiency of the collateral coronary circulation as well as relieve pain; moreover, patients are not deprived of a warning signal when the coronary circulation is overtaxed, although the sensation experienced is rarely described as pain.

Inheritance of Werdnig-Hoffmann Paralysis

Q.—A couple whose first two children died in the first year of life as a result of progressive spinal muscular atrophy (Werdnig-Hoffmann paralysis) are naturally apprehensive about having another child. What advice should be given? Having regard to normal marital relations, is sterilization of the wife indicated?

A.—Inheritance of this disease is recessive, and the chance that any subsequent child will be affected is one in four. If the parents should feel—as they well may—that this is a risk that they dare not face, there is undoubtedly a case for sterilization. The writer believes that in Denmark, where enlightened eugenic laws have been in operation for some years, sterilization would be granted in this instance if the parents requested it. There is, however, no more reason for sterilizing the wife than the husband, for both are transmitting the gene. One point should be remembered, perhaps: should the sterilized partner chance to remarry, and hence the risk of the defect's appearing be reduced to negligible proportions, he or she might regret having taken such a step. It should also be understood that this is the medical answer to a medical question and does not pretend to deal with the legal and ethical considerations which obviously arise.

Testosterone in Gynaecomastia

Q.—Arising out of the question about adolescent gynaecomastia (Nov. 27, 1948, p. 968), what dosage of methyl testosterone, and what method of administration, would you recommend for a boy of 15 who is considerably embarrassed by enlargement of the breasts. He is already 6 ft. 1½ in. (1.84 metres) tall, and one hesitates to use a preparation which may stimulate growth still further. He is also well developed sexually, and one wishes to avoid excessive stimulation of the sex organs.

A.—The usual dosage of methyl testosterone is 5 mg. three times a day. This may result in some increase in size of the penis and some erections, but these effects are more likely to occur in hypogonadism than when sexual development is normal. The same is true of the accelerating effect of methyl testosterone on growth. If testosterone propionate is given in very large doses, however—for example, 50 mg. injected daily—it has a tendency to accelerate union of the epiphyses. In the particular case in question, local inunction of testosterone ointment, 25 mg. per gramme, should be a safe procedure, limiting the total dosage to 100 mg. weekly. Testosterone therapy is based on the theory that the gynaecomastia is due to an actual or relative excess of oestrogens, the source of which may be the adrenal cortex. There is experimental evidence that, in some species at least, the breast is also stimulated by androgens, and by the anterior pituitary gland itself in the absence of the gonads, so that the problem is a complicated one.

Respiration in the Newborn

Q.—Could you explain exactly how the work of Sir Joseph Barcroft proved the value of convulsant drugs in asphyxia neonatorum?

A.—Sir Joseph Barcroft's book *Researches on Pre-natal Life* discusses in the last chapter the onset of respiratory movement in the newborn. There is no reference to the use of convulsant drugs, and the answer to the question therefore appears to be that Barcroft's work did not prove the value of such drugs in asphyxia neonatorum. The chapter describes the development of respiratory movements in the foetal sheep. By the 38th day the movements evoked by a tap on the face, between the eye

and the mouth, extend to the diaphragm, but only as an item in a generalized movement. After the 40th day the response of the foetus to a tap is not merely a spasm but a rhythm of successive spasms, increasing in number and rate as days go by; the intercostals then begin to contract. In the next stage, after the 45th day, the response to stimulation is an initial movement of the body followed by an after-discharge which resembles a respiratory rhythm. Thus the respiratory movements are separated in time from the body movements, but are still part of a response to a stimulus. Between the 50th and 60th days there is a change from a condition in which rhythmic movements of the chest come and go with little obvious cause to one in which the foetus has become inert. It can, however, be thrown into activity by occlusion of the umbilical cord. No further change takes place till birth. Only when this state of inhibition, which persists for the second half of gestation, has been reached does occlusion of the cord start respiratory movements. The inhibition is exerted from a level at least as high as the posterior corpora quadrigemina. From the time of onset of inhibition, Barcroft says that the issue "whether the foetus did or did not exhibit respiratory movements depended on whether stimulation or inhibition had the upper hand." When the foetus is delivered, a flow of sensory impulses beats upon the brain and must exert a profound effect in raising the general sensitivity of the central nervous system.

From the foregoing it could be argued that if the stimulation of birth is not enough to overcome the inhibitory impulses acting on respiration, then the injection of a convulsant drug might serve to tip the balance and start respiration.

NOTES AND COMMENTS

Water-pitressin Test in Epilepsy.—Lieutenant-Colonel M. CHANDRA (Jullundur City, India) writes: With reference to the question and answer regarding the water-pitressin test in epilepsy ("Any Questions?" Feb. 12, p. 291), I have notes on 24 cases on whom this test was carried out in the M.E.F. in 1945-6. Eighteen had epileptic fits during the test. In most the fits came on during the course of the first three or four injections of pitressin, provided a positive water balance had been established first, before injections were started. I found that if cases tested were close together in a group the hysterics—seeing the epileptics and determined not to be outdone—had sorts of fits as well. This vitiated the value of the test, especially if the description of the fits given by the nursing staff was vague. So the value of the test is enhanced if the suspects are tested singly and if they do not know what is coming to them. Some epileptics, after having a fit during the test, carried on afterwards having frequent fits. These were controlled by dehydration and sedatives.

Horse-riding for the Infirm.—Dr. W. J. HASTINGS SAYERS (Edinburgh) writes: I have become interested in the possibility of horse-riding for the infirm. I have noticed of late in various journals advertisements, both "For Sale" and "Wanted," of mounts suitable for the infirm rider. Whilst on war service I remember seeing an elderly gentleman, who was recovering from a heart attack, riding in the manège. The appearance of ease on the part of the rider whilst cantering has caused me to wonder if carefully regulated riding might not be made use of early in the convalescence of certain types of patients. I would like to see the cob becoming as indispensable to the lame as the dog has become to the blind—both can become more independent of their fortunate neighbours. Possibly if the infirm horsemen were less individualistic it would not be necessary to write this letter. I wonder if any of your contributors could help me, either from personal experience or observation. I am particularly interested in the possibility of riding for a patient with paralysis due to disseminated sclerosis, who wishes to visit in the country places where no invalid carriage or car will go.

THE SECRETARY REPORTS

SENIOR HOSPITAL OFFICERS

It is perhaps one of the dangers of a comprehensive National Health Service that some of the main difficulties arise not from the wording of the Act or its more important regulations but from the twists and turns of the bureaucratic machine. It has been said of big administrations that, composed as they are of kindly and thoughtful men who would not harm a cat, let alone a fellow human being, once they go into action as an aggregation of kindly human beings they become, through the machine, capable of unfairness, harshness, and indeed cruelty of a kind which as individuals they would promptly disown. One recalls that the London County Council, having committed itself to the principle of adapting the remuneration of its district medical officers in any one year to the number of items of service undertaken in the previous year, discovered that in a year of unprecedented bombing certain D.M.O.s in Central London had put in a reduced number of items of service. Disregarding the fact that these D.M.O.s were required to continue to live at their peril in these dangerous areas, ignoring the fact that a night visit which counted as one on the record might involve dangerous hours in the black-out exposed to bombing, the council proceeded to reduce the remuneration of these D.M.O.s by applying the customary mathematical formula. Fortunately an inspector of the Ministry of Health was wiser, and the proposed reduction was ruled out.

Are we in for similar twists of the administrative screw? The senior hospital officer grade was put forward by the Ministry as a necessary one, bearing in mind that a proportion of the members of hospital staffs taken over on the appointed day would not be classified as specialists or as trainees. Thus a reasonable case for the grade was made out. But already there are signs of a move to make new appointments to this grade, practitioners of specialist rank being invited to apply for posts with this non-specialist grading and remuneration. An innocent proposal immediately becomes a dangerous one. If anything is done directly or by implication to create two types of specialist—the full specialist and the sub-specialist—the hospital service of the country will suffer. If the senior hospital officer grade is to serve its intended purpose without damaging future quality the grade must be a declining one, no new appointments being made to it, or, if such appointments are made, only appointments within a defined field, there being no circumstances in which those of specialist status are invited or appointed to posts in this grade. It may well be that the best of motives lie behind the current tendency to continue and expand the senior hospital officer grade. But good intentions have often led to warmer places. It is with these considerations in mind that a decision has been reached not to accept for publication in the *British Medical Journal* advertisements for hospital appointments involving specialist duties which state or suggest that the successful candidate may be placed in the senior hospital officer grade.

Public Health

There is nothing to report on the public health front. As yet the associations of local authorities have shown no sign of agreeing to the opening of negotiations for public health remuneration through Whitley machinery. We for our part continue to decline advertisements for whole-time public health posts which do not conform to our own recommendations. Some local authorities are seeking to circumvent their difficulties by inviting general practitioners to undertake public

health work on a part-time basis. No doubt any general practitioner so invited will appreciate the importance of taking no steps which would make more difficult the task of the Association in defending the interests of the Public Health Service. On this issue of Whitley machinery and arbitration all branches of the profession are concerned, and they must stand together.

Dispensing Practitioners

Our postbag reveals that there is a good deal of doubt about the circumstances in which a practitioner becomes a dispensing practitioner, and even more doubt about the choice which is presented to every dispensing practitioner between accepting the annual dispensing capitation fee and securing remuneration on the basis applied to the chemist.

There are two circumstances in which a practitioner may be called upon to supply drugs and appliances—that is, to become a dispensing practitioner—to a particular patient. First, the patient may satisfy the local executive council that, by reason of distance or inadequate means of communication, he would have serious difficulty in obtaining drugs and appliances from a chemist; secondly, that he is resident in an area regarded by the local executive council as rural, at a distance of more than a mile from the premises of a registered chemist.

If, in either of these circumstances, the patient applies and the doctor agrees, the doctor becomes a dispensing practitioner in relation to this patient. In the absence of the doctor's agreement the local executive council may require a practitioner to dispense for a patient covered by one or other circumstance, the practitioner being exempted from the requirement on satisfying the local executive council that he is not in the habit of supplying drugs to his patients or that, in a case in which distance is the criterion, the patient can with reasonable facility obtain drugs and appliances from a chemist. The practitioner has the right of appeal to the Minister.

Where a practitioner has arranged or is required to supply drugs and prescribed appliances, he may elect to be paid on the basis of the actual drugs supplied, plus a dispensing fee, or he may elect to receive a capitation fee in respect of each "dispensing patient" to cover the liability of supplying drugs and prescribed appliances (with additional payments for specially expensive items). The dispensing capitation fee is at the rate of 6s. 6d. per year in England and Wales and 5s. in Scotland. The capitation fee method of remuneration is perhaps more straightforward for those moderate mathematicians who have not studied the official Drug Tariff ("Provisions relating to the Calculation of Charges for Drugs, Preparations Containing Drugs, and Appliances Supplied to National Health Service Patients").

The other method, though perhaps more cumbersome for the dispensing doctor, has some features to commend it, and incidentally some curious anomalies. In Scotland, I am told, the dispensing practitioner who opts to be remunerated on the same basis as the chemist may receive 1s. 3d. for supplying 1 lb. of bicarbonate of soda in bulk, while for dispensing a single powder of 10 gr. of the same ingredient the fee is 2s. In both cases an additional fee of 2½d. is payable for the container. Similarly, one teething powder costs ½d., plus 2s. dispensing fee, plus 2½d. for the container—that small piece of paper which so often is blown away when a door or window is opened. For ointments and creams the dispensing fee is 1s. 3d., for tablets or pills 1s., for non-proprietary mixtures 1s. 6d., plus in each case the container fee of 2½d. For proprietary articles the dispensing fee is 1s. It is for the dispensing practitioner to select the method of remuneration which he prefers.

National Health Service

PROPOSED CUT IN DENTISTS' FEES

The Minister of Health has informed the dental associations that a reduction of 25% of the gross earnings of dentists in the Service would be justified. The dental associations have declined to meet the Minister to discuss the reduction pending the issue of a report by the working party which is investigating the timing of dental operations.

MATERNITY OUTFITS

A patient being confined at home and wanting a maternity outfit should be advised to call at the nearest welfare clinic, or, if this is not possible—e.g., in remote rural areas—to write to the local health authority.

BIRTH DATES ON MEDICAL CARDS

Following representations made by the General Medical Services Committee, the Minister of Health has asked local executive councils to enter the date of birth of each person on the medical record card before it is sent to the doctor.

CLASSIFICATION FOR MILEAGE PAYMENTS

The Ministry of Health has informed executive councils that a classification of practices for the purpose of mileage payments is contemplated. It will be similar to that under the N.H.I. Act—rural practices (A), semi-rural practices (B); and urban practices (C). To determine the classification of any practice the total number of persons on a doctor's list is divided by the total number of mileage units credited to him. If this calculation results in a figure less than 0.75 the practice should be classified (A); if between 0.75 and 2.5, (B); if over 2.5, (C).

OPHTHALMIC SERVICE INQUIRY

The Minister of Health has set up a working party to carry out an inquiry into the length of time taken for ophthalmological examination, and has appointed as chairman Mr. W. Penman, F.I.A., past-president of the Institute of Actuaries. The Association and the Faculty of Ophthalmologists have nominated the following as members of the working party: Mr. G. W. Black, Dr. J. J. Healy, Mr. O. Gayer Morgan, Dr. R. Gordon Simpson.

The fee for examination by an ophthalmologist under the Supplementary Ophthalmic Service was reduced by the Government from £1 11s. 6d. to £1 5s. a case in spite of the protest of the Association and before any inquiry had been made into the average length of time necessary for ophthalmological examination under the scheme.

The fee of £1 11s. 6d. was based on the assumption that two cases would be examined in one hour, the rate being £3 3s. an hour, thus implementing generally the Spens recommendations on specialists' remuneration.

By reducing the fee to £1 5s. the Ministry assumed that more than two cases could be examined in one hour—in other words, twenty-four minutes would be the average time for each case.

The working party has started the inquiry, and the Minister has promised to readjust the cut fees retrospectively if the inquiry shows that to be necessary.

The names of doctors who give information will be confidential to the working party, as will the details they supply.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar.

Non-County Borough Councils.—Dartford, WallSEND.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huxton-with-Roby, Redditch (restricted to new appointments), Tyldesley.

SCOTTISH CONSULTANTS AND SPECIALISTS COMMITTEE

Members of the Central Consultants and Specialists Committee (Scotland) at a meeting at B.M.A. House, Edinburgh, on April 25 considered the Government's proposed terms and conditions of service of hospital medical and dental staffs. The meeting had before them comments received from regional consultants and specialists committees. Various resolutions were passed for consideration by the Central Committee.

Betterment

In regard to specialists, it was decided that the betterment factor was unsatisfactory and should be accepted only without prejudice to future negotiations, and that the matter be left to the Joint Committee subject to this proviso.

The committee regretted the absence in the proposals of any recognition of the principle of responsibility payment and considered that this omission should be corrected, either by modification of the Distinction Award system or otherwise.

During the discussion on trainee specialist grades objection was taken to the use of the word "trainee," the view being expressed that it was inappropriate to have young persons entered as specialists in training when only about 25% would go on to specialist practice. The committee resolved to recommend that the class described as Grade 3 Trainee Specialists should be abolished and replaced by an additional category to be known as Senior House Officers, entitled to the same salary and conditions as defined for Grade 3 Trainee Specialists.

Senior Hospital Medical Officers

In connexion with the grade for senior hospital medical officers, the chairman, Dr. I. Simson Hall, said it had been made clear by the Department of Health for Scotland that this grade was expected to be a diminishing one, intended for those who were content to take senior posts not of specialist rank. There were certain transferred local-authority medical officers whose appointments could appropriately come within this grade. The committee felt that so far as possible no further appointments of this type should be made.

Medical Superintendents

In considering the proposals for medical superintendents and deputy medical superintendents the committee had before it the report of a special subcommittee. The view of the subcommittee was that the proposals as they stood could only lead in time to the elimination of the role of medical superintendent in the field of hospital administration. This would mean the end of the traditional system in Scottish hospitals, and in the view of the subcommittee would be contrary to the best interests of the hospital service. It was considered wrong in principle and unwise in practice to determine in this oblique fashion what should be determined directly and on merit—namely, the future of medical superintendents.

The report was accepted.

The committee endorsed the view expressed by the Western Regional Consultants and Specialists Committee that the fee for obstetric operations be 6 guineas for a minor and 10 guineas for a major operation.

Clinical Teachers

The committee felt that the position both of whole-time and of part-time clinical teachers was far from satisfactory. In particular, it was felt to be unacceptable that the determination of what was appropriate remuneration for the teaching duties of part-time clinical teachers should be left solely to the university or teaching school.

It was reported that at a meeting with representatives of the Department of Health Dr. Simson Hall had asked for an assurance that, after the permanent contracts had been presented to the individual specialists, a reasonable period would be allowed for them to consider the terms offered and, if dissatisfied, to discuss them with the regional hospital board concerned. Sir George Henderson, for the Department, hoped that by the time

the actual contracts were issued individual specialists would for the most part already have been made aware of the terms offered.

In connexion with the other items in the proposed terms, the representatives on the Central Committee were asked to support resolutions from the various regions in England which coincided with the views of the Scottish Central Consultants and Specialists Committee.

Questions Answered

Request for Proprietary Preparation

Q.—*The mother of an N.H.S. patient subject to chronic asthma brought a pamphlet from a chemist saying they could obtain a certain proprietary remedy or anything else by getting a prescription from their doctor. I did not consider it necessary. Am I in order in refusing?*

A.—A practitioner is required to render to his patients all proper and necessary treatment, but the actual treatment and drugs prescribed are entirely at the doctor's discretion. A practitioner is therefore quite in order in refusing to prescribe a proprietary remedy which he considers is not necessary for the proper treatment of his patient.

Employment of Doctor's Wife

Q.—*If a doctor pays his wife for services rendered in the conduct of his practice, must he stamp a card for her?*

A.—No, under the National Insurance Act employment of a wife by her husband, or vice versa, is not employment within the meaning of the Act, and no contributions (employer's or employee's) are payable.

HEARD AT HEADQUARTERS

Reception to Swedish Medical Society

On May 2 the President and Council gave a reception in honour of the Paediatric Section of the Swedish Medical Society, whose members were visiting London at the invitation of the British Paediatric Association. The guests were received in the Old Library by Sir Lionel and Lady Whitby. Films of paediatric interest were shown in the Hastings Hall, and there was a small exhibition of objects of interest in the Members' Common Room. These included a handsome volume presented by the Swedish Medical Society on the occasion of the opening of B.M.A. House in 1925; a gavel made from Charles Dickens's mulberry tree, which was cut down to make way for the South Wing; an unofficial *Medical Register* of 1783 containing the name of Edward Johnstone, M.D., of Birmingham, who in 1832 became first President of the Provincial Medical and Surgical Association (forerunner of the B.M.A.); and a historical exhibit tracing the development of the *Journal* from the *Transactions* of the Association, which were first published at its foundation. On the same evening Pandit Nehru was the guest of the India League at a reception in the Great Hall.

Do They Know?

The Association is making further efforts to dispel the public's ignorance of what everyone pays towards the cost of the Health Service and how much the doctor gets out of it. It is sending a leaflet to every general practitioner in the Service, who can obtain from the Association as many copies as he wants for distribution to his patients. It makes the point that the doctor gets just 44d. a week for looking after a patient for a year; out of that he must pay for his surgery, his equipment, his transport, and part of his pension. About 1d. comes from the employed worker's insurance contribution and 34d. from taxes. As the Gallup Poll showed recently (*Supplement*, April 16, p. 229), a large number of people still think that the whole insurance contribution goes to the doctor. This leaflet will help them to understand what happens to their money.

Correspondence

Specialists and the Health Service

SIR.—Your leading article (*Journal*, April 23, p. 717) on the dual obligation undertaken by the President of the Royal College of Physicians in acting also as the chairman of the Distinction Awards Committee concerns but one of the causes of uneasiness among specialists as to their present position. The high hopes aroused at the A.R.M. of last June by the constitution of the Central and Regional Consultants and Specialists Committee, that at last specialists, like the general practitioners, would have their affairs determined in a unified and democratic manner, have not been fully realized. For the Central Consultants and Specialists Committee at once became subordinated to a Joint Committee with the Royal Colleges and Scottish Corporations, with the democratically elected element in a small minority; and in consequence older representative associations of specialists, such as that of the staffs of the major non-teaching hospitals, recognized a breach of faith on the part of the B.M.A. and felt obliged to continue and to act independently. Moreover, there have been indications that eminent individuals have continued to advise the Minister without instruction from the profession, and that the College councils, true to their oligarchic constitutions, have been, as in the case of the distinction awards, willing to approve of a matter of great importance without waiting to learn the views of the specialists in general or even of their own Fellows.

There are a number of features in the proposed terms and conditions of service for specialists which may imperil their freedom and perhaps lower the status and income of many who are at present doing specialist work. It is hoped that negotiation will alter these features; but it seems likely now that the method of remuneration, including the distinction awards, as proposed in the Spens Report will be implemented. Specialists should realize what the application of this method will mean, for it may well be that widespread discouragement and discord will be a result. It should be noted that the method makes no additional allowance of salary for seniority over the age of 40 in a branch of the profession in which length of experience is particularly valuable and maturity in knowledge and skill are not usually reached before the age of 50. Nor is there allowance for the great difference between the specialties in length of training, degree of responsibility, arduousness of work, and age to which work can be carried on. Notwithstanding the wide differences in the past between incomes in the specialties, all specialists will in this method be paid on the same basis, and after the age of 40 all but those receiving distinction awards will be on the same income level.

The distinction awards of additional remuneration for one-third of specialists have been called an "imaginative" method of providing incentive and reward to those of extra ability. In fact, no more certain way of causing discouragement and disharmony among hospital staffs could have been conceived. Based on a false assumption that a specialist requires the incentive of extra pay to seek distinction in his work or that extra pay is a proper kind of reward for distinction in a scientific profession, and incurring the risk of a certain element of patronage, the method of awards may well prove to be not capable of application in the fair and even way idealistically envisaged by the Spens Committee. While it may be possible for the Awards Committee to select the few specialists for the top grade without difficulty, it is inconceivable that the committee, which, it may be noted, in its present composition contains at most one member connected with the non-teaching hospitals, could even with the aid of regional subcommittees select properly from among some thousands of specialists 50% who could be said to be better than their colleagues. The result of such selection among hospital staffs is not hard to imagine.

It has been said that if this method of remuneration does prove to be unpopular it can be changed. But it may not be easy to do so, for the awards are to be bound up with superannuation and apparently will be given not for a term but for the whole length of the contract. It would seem that to alter or withdraw the method would mean a breach of contract. It would be wise therefore for specialists to ask themselves

again whether this and other features of the terms of remuneration proposed for them will really provide them with incentive and contentment in their work and make for harmony with their colleagues. In my view also they should not enter into permanent contracts until the amending Act has been passed, for that Act should include provisions to secure the specialist from becoming a whole-time officer and that he will have a proper part in the administration and development of the Service; also to ensure that facilities will be continued for private practice, for on the preservation of that alternative his freedom must ultimately depend. If such points are not secured before the contracts are signed, it may be difficult to secure them later.—I am, etc.,

Provident Scheme for Medical Men

SIR.—It will, I believe, be of interest to your readers to learn that the British United Provident Association has recently extended its service by providing a special range of scales for medical practitioners. B.U.P.A. is a non-profit-making mutual-aid organization whose object is to relieve from financial worry all who in the event of serious illness would want private specialist and in-patient treatment. It has been represented by medical men from various parts of the country that their needs differ from those of the general public, in that the cover they require for themselves and their families is normally against maintenance charges only.

This is the position which the new scales are designed to meet. It is our hope that they will provide a solid sense of assurance to a section of the community which inevitably is especially aware of the anxieties attendant on serious illness.

Full particulars will be supplied on application to the Association's Registered Office, Provident House, 61, Bartholomew Close, London, E.C.1

London E.C.1

A. H. ROWELL,
Chairman

Delivery of Cars

SIR.—I enclose a cutting from one of to-day's papers advertising a post-war car for sale because the owner has just taken delivery of his new car. I would like to point out that I own a similar make of car which is now well into its eleventh year and has done over 80,000 miles. I am on the waiting-list for a new car (since July, 1947), and have recently been told by the makers with much rudeness that there is no chance of my obtaining delivery of a new car this year unless I can obtain a certificate that my present car is no longer roadworthy.

I have had to spend over £200 during the past two years to maintain my car in a roadworthy condition, and cannot afford to continue in this way. Is it not about time that the B.M.A. pressed for an inquiry to be held into the delivery of new cars by manufacturers? It would seem that being on the B.M.A. priority list means nothing at all.—I am, etc.,

Moor Park, Herts

Association Notices

SCOTTISH COMMITTEE

1949-50 Session

Election of three representatives by the Group of eight Divisions comprising Orkney, Shetland, Caithness, Sutherland, Inverness, Outer Islands, Ross and Cromarty, and Argyllshire.

In accordance with the Standing Orders of the Scottish Committee nominations for these three vacancies shall be in writing and may be made (a) by a Division or (b) over the signatures of not less than three members in the grouped Divisions. Nomination under (a) does not invalidate nomination under (b) or vice versa. Nomination forms have been sent to the Honorary Secretaries of the Divisions in the Group, and can also be obtained on application to the Scottish Office. If more than three members are nominated the election shall be by voting papers sent by post from the Scottish Office to each member of every Division in the Group. Nominations should be sent to me at the Scottish Office, 7, Drumsheugh Gardens, Edinburgh, not later than Saturday, May 28, 1949.

E. R. C. WALKER,
Scottish Secretary.

PROPOSED DISSOLUTION OF LANCASHIRE AND CHESHIRE BRANCH AND THE FORMATION OF A "MERSEYSIDE" BRANCH AND A "MANCHESTER" OR "LANCASHIRE AND EAST CHESHIRE" BRANCH

Notice is hereby given by the Council to all concerned of a proposal made by the Council of the Lancashire and Cheshire Branch that that Branch should be dissolved; that two new Branches should be formed—namely, a "Merseyside" Branch, and a "Manchester" or "Lancashire and East Cheshire" Branch; and that the area of the proposed new Branches should be coterminous with that of the following Divisions of the Lancashire and Cheshire Branch:

"Merseyside" Branch: Birkenhead and Wirral, Cheshire, Liverpool, St. Helens, Southport, Wallasey, Warrington;

"Manchester" or "Lancashire and East Cheshire" Branch: Ashton-under-Lyne, Blackburn, Blackpool and Fylde, Bolton, Burnley, Bury, Crewe, Furness, Hyde, Lancaster, Leigh, Macclesfield and East Cheshire, Manchester, Mid Cheshire, Oldham, Preston, Rochdale, Salford, Stockport, Wigan.

Any Division or member affected by the proposed changes and objecting thereto should write to the Secretary of the Association by June 14, 1949, stating the objection and the ground therefor.

CHARLES HILL,
Secretary.

Branch and Division Meetings to be Held

DARTFORD DIVISION.—At Nurses' Recreation Room, Livingstone Hospital, Thursday, May 19, 8.45 p.m., annual general meeting.

EAST YORKSHIRE BRANCH.—At the Trocadero Restaurant, Silver Street, Hull, Wednesday, May 18, 7.30 p.m., annual general meeting preceded by a Supper. Agenda: Instruction of Representatives to Annual Representative Meeting at Harrogate, etc.

HENDON DIVISION.—At Hendon Hall Hotel (Ballroom), Wednesday, May 18, 8.30 p.m., joint meeting of Division with Hendon and Edgware Branch of Pharmaceutical Society of Great Britain. Film: "Sulphonamide Therapy." Principal speaker, Dr. E. W. Tapley. Members are invited to bring guests.

MARYLEBONE DIVISION.—At Medical Society of London, Chandos Street, London, W., Tuesday, May 17, 8.30 p.m., general meeting. Agenda: To report on Special Representative Meetings on March 29 and 30; Consideration of motions and amendments for Annual Representative Meeting, etc.

METROPOLITAN COUNTIES BRANCH.—At B.M.A. House, Tavistock Square, London, W.C., Thursday, May 26, 8 p.m. for 8.30 p.m., Charities Ball. Tickets, including a buffet supper, 2 guineas each, obtainable on application to the Secretary, the Charities Ball Committee, Metropolitan Counties Branch, B.M.A. House.

METROPOLITAN COUNTIES BRANCH.—At B.M.A. House, Tavistock Square, London, W.C., Tuesday, June 7, 2.30 p.m., annual general meeting. Agenda: Induction of Dr. C. G. Martin as President of the Branch and President's Address, etc.

NORTHERN IRELAND BRANCH.—At New Nurses Homes, Royal Victoria Hospital, Belfast, Wednesday, May 18, annual meeting.

SOUTH-WEST ESSEX DIVISION.—At Clinic Hall, Thorpe Coombe Maternity Hospital, Forest Road, Walthamstow, E., Wednesday, May 18, 8.30 p.m., lecture by Professor A. Moncrieff: "Some Diseases of the Newborn."

Meetings of Branches and Divisions

SOUTH BEDFORDSHIRE DIVISION

At a meeting held by the South Bedfordshire Division on April 22 Mr. Peter Casson gave a talk on "Hypnotism," which was followed by a demonstration.

ANNUAL MEETING BANKING FACILITIES

The Westminster Bank will have a temporary office at the exhibition to be held at the Association's Annual Meeting at Harrogate this year.

EDWARD JENNER: THE MAN AND HIS WORK

BY

E. ASHWORTH UNDERWOOD, M.A., B.Sc., M.D., D.P.H., F.L.S.

Director of the Wellcome Historical Medical Museum

The two-hundredth anniversary of the birth of Edward Jenner, "the discoverer of vaccination," was celebrated on Tuesday, May 17, and the time is opportune for a brief review of Jenner's life and the beginning of the new idea which he inaugurated, and which he was fortunate in seeing widely established in his lifetime. No man has suffered more from the excessive eulogy of well-meaning friends and later admirers, or from the invective of those who for some reason or other did not subscribe to his views.

Early Life

Edward Jenner was the son of the Rev. Stephen Jenner, rector of Rockhampton and vicar of Berkeley, in Gloucestershire. Born on May 17, 1749, he was educated at first at Wotton-under-Edge under a Mr. Clissold, and then went as a pupil of the Rev. Dr. Washbourn at Cirencester. When he was 5 his father died, and the boy was looked after by his elder brother, who was also in Holy Orders. It was decided that Edward was to practise medicine, and at the age of 13 he was apprenticed to Daniel Ludlow, a surgeon of Sodbury, near Bristol. In 1770 he became a student at St. George's Hospital, London, and was for two years a house pupil of John Hunter. During this period a warm friendship sprang up between master and pupil, and after Jenner left London he and Hunter corresponded regularly for 20 years—until Hunter's death in 1793. Jenner's letters to Hunter have all been lost or destroyed. But Jenner preserved carefully Hunter's letters to him. They are now in the Royal College of Surgeons, and were printed by Baron in his biography of Jenner. The correspondence was occasioned by the fact that Jenner was no longer in London. In 1772 Jenner left London and settled in his native town of Berkeley as a country practitioner.

It should be said that this translation appears to have been made because he wanted to be a country practitioner. He had many of the qualities which are essential to a successful physician or surgeon in town. He had had a long training in a practice which probably gave him plenty of experience, and he had been a favourite pupil of the great John Hunter. Statements are still being made that Jenner was not "a doctor." This is of course nonsense. If by "doctor" is meant a man who has qualified for a doctorate in medicine, then a considerable proportion of those who legally—and successfully—practise medicine to-day would not be entitled to this appellation. In Jenner's time this entry by apprenticeship was the normal course of training for all general practitioners—that is, "doctors." It is true that Jenner did become later on M.D. of St. Andrews University, and that he did not sit any examination or present any thesis for the degree. But this was also quite a usual practice, and many other famous men have obtained

their doctorate in the same way and at the same university. Jenner never became a Fellow of the Royal College of Physicians. He was asked to do so, but by the iron ruling of the statutes he could not be admitted without sitting an examination in Latin—and this trial he declined to undertake.

Jenner as a Country Practitioner

It was certainly his deep love of the country of his birth which induced Jenner, to return to it and—with brief exceptions—to spend the remainder of his days there. He was by birth and breeding a countryman. He soon settled down in practice, and took an interest in what we would now term "current medical literature." He joined a medical society at Alveston, near Bristol, and was largely instrumental in the founding of a similar society at Rodborough. To the meetings of this latter society he contributed papers—especially one on ophthalmia and another on angina pectoris. There is every reason to believe that Jenner was a conscientious and successful practitioner. He also took an interest in music, played the flute and violin, and was a good fellow at social gatherings.

Jenner as a Naturalist

Love of nature was instilled into Jenner from his earliest years. We do not hear about it during his apprentice years, but when he was a pupil of John Hunter an event occurred which might have altered the course of his life. Captain Cook returned from his first voyage to the Pacific in 1771. A "Mr. Joseph Banks"—later Sir Joseph Banks, president of the Royal Society for 41 years—and a Swedish naturalist, Dr. Solander, had accompanied Cook on the voyage and had brought back a very large collection of botanical and zoological specimens. Edward Jenner was offered the job—no doubt a part-time one—of arranging the botanical specimens, and he did it well. According to one account he was even offered the post of naturalist to Cook's next expedition—but this could hardly have been the case.

When Jenner returned to Berkeley he carried on with his natural history pursuits, and from Hunter he received not only encouragement but repeated and insistent demands for specimens. We read of requests for the nests of various birds, a nest with a cuckoo's egg in it, for hedgehogs, and for all the many other animals or objects which John Hunter required in the course of his experiments. He even asked for a bustard—then becoming a rare bird—and got it. Jenner also carried out experiments under Hunter's directions. It was in a letter replying to comments or suggestions which Jenner had made that Hunter gave him the famous advice: "But why think? Why not try the experiment?"

In 1783 Hunter suggested to Jenner that he "must pursue the cuckoo this summer," and asked for "a true and particular account" of that bird. Jenner carried out his

FIG. 1—The Old Vicarage at Berkeley, in which Jenner was born

observations over a few years, and these resulted in a paper which was published in the *Philosophical Transactions of the Royal Society* in 1788 and for which Jenner was elected a Fellow in 1789. This paper contains many original observations of importance—especially those in which he describes how the young cuckoo actually throws its foster-brothers, or the eggs of its foster-parent, out of the nest. He described the extreme sensitivity of the wing tips of the young cuckoo during the performance of this operation, and also the fact that it has a depression between its scapulae which appeared to him to be designed to assist the performance. When the young cuckoo was 12 days old this depression had entirely disappeared. Accepted rather sceptically after their publication, these observations of Jenner's were supposed during the middle of the nineteenth century to have been quite discredited. In the last thirty years the acuteness and accuracy of Jenner's work have been vindicated—largely by the aid of photography.

In his later years Jenner took up the question of the migration of birds. He gave instances of various birds having been seen far out at sea, and showed that the same

birds will return to the same place one summer after another. This paper was published in the *Philosophical Transactions* in the year after his death.

Smallpox and Inoculation

The incidence of smallpox in this country reached its peak in the eighteenth century. Although there were outbreaks all over the country, it was in London that the disease showed such a constant prevalence. In the 80 years between 1721 and 1800 the annual deaths from smallpox in the Metropolis were less than 1,000 in only five individual years. In 1772 it caused 3,992 deaths in London. But the pock-marked faces of so many dwellers in the great city bore striking witness to the prevalence of the disease—in contradistinction to its mortality.

The practice of inoculation for preventive purposes was well recognized during the second half of the eighteenth century. The "prevention" desired was of course that from

death, and not from the disease, which was transmitted during the operation to the individual to be inoculated. Inoculated smallpox was often fairly mild, and the theory was that it was better to obtain protection as a result of a mild attack at a convenient time than to risk a severe and possibly fatal attack when one wanted it least. Practised in the East from ancient times, inoculation was introduced into this country by Timoni (1714) and by Pylarini, and a renewed effort to popularize it was made by Lady Mary Wortley Montagu (1721), who had just returned from seeing it performed in Constantinople. After 1738 the practice increased, but nothing could get over the fact that the inoculated disease was often not mild and deaths were not infrequent. In 1840 the practice of inoculation became illegal.

The Beginnings of Vaccination

While he was an apprentice at Sodbury Jenner was struck by the fact that a young countrywoman had said that she could not take smallpox because she had had cowpox. He mentioned this curious statement to John Hunter, but the latter was apparently not interested. Years later Jenner began to collect examples of persons whom he could not inoculate successfully because they had had cowpox at some time during the course of their lives. Even at this early stage he seems to have been obsessed by the feeling that cowpox *ought* to give complete and permanent immunity to smallpox. This is indeed strange, since every practitioner knew that smallpox did not always give complete and permanent protection against itself. By this time John Hunter was dead, and there was no one of his experience and acuteness with whom Jenner could discuss the matter.

Jenner therefore set out to show that cowpox protected against smallpox, and also that cowpox could be transmitted from one human being to another just as smallpox could.

There should be no misconception of what was in Jenner's mind. Though his arguments and deductions are possibly not too well expressed, his line of thought clearly was constructive and of considerable originality. It was one thing to show that a person who had had a natural attack of cowpox was thereafter possessed of considerable immunity to smallpox

FIG. 2—Chantry Cottage, Berkeley, in which Jenner lived most of his life and died

EDWARD JENNER (1749 - 1823)

This is a photograph of the original pastel portrait (now in the Wellcome Historical Museum) made by J. R. Smith in 1800 and exhibited in the Royal Academy in that year. It is now reproduced for the first time by the courtesy of the Museum.

Cowpox was a disease of cows, and only a fraction of the population ever has any direct contact with these animals. Furthermore, cowpox was present only in certain counties of England, and only at intervals. It was quite another thing to set out deliberately with the intention of showing that cowpox, naturally acquired, could be transmitted artificially from person to person so that there would result an increasing reservoir of persons who had been given the opportunity of becoming invulnerable—or "immune," as we would say—to smallpox. There is no doubt that this was what was in Jenner's mind. At a later date opponents of his views put forward counter-claims to priority. For example, there was the case of Benjamin Jesty, a farmer who twenty years before had inoculated his wife and children with cowpox to prevent them from contracting smallpox. But Jesty had no notion of perpetuating the cowpox from one individual to another. This was the cardinal factor in Jenner's doctrine, and it was an idea which had probably not occurred seriously to anyone before; at least, no one had ever attempted to put it into practice.

Once this point is clearly grasped certain interesting questions arise. To show the pitfalls in Jenner's path it is sufficient to take one example. Only a few months after the publication of his famous book Jenner sent to a friend in London some lymph from the cowpox vesicle on a child's arm. The lymph was dried and preserved in a quill. Before long people were discussing the methods of transmitting lymph to a distance—dried on lancets, and in other ways. If lymph from the human pock could be stored and transmitted in this way, why could not lymph from the pock on the cow? After all, this is essentially the method which we use to-day. The answer appears to be that Jenner was impressed early in his investigations by the fact that there are two types of cowpox in the cow—the true disease, and another form which he called "spurious cowpox." We now know that this view is wrong; but Jenner believed it, and he also believed that the spurious type does not give immunity to smallpox. On the other hand, true cowpox in the human bred true. He was therefore afraid that if the practice of using dried lymph from cows was widely adopted numerous failures might result. There was also the possibility that septic diseases might be transmitted or that the lymph might be taken at the wrong time. Difficulties of this type must have caused Jenner much reflection—and are ignored by many who are wise 150 years after the event.

The Inquiry

In May, 1796, Jenner found that the dairymaid Sarah Nelmes had a "typical" cowpox lesion on her finger, and on the 14th of the month he inoculated the boy James Phipps with matter from this lesion. The local result was similar to that following variolous inoculation. On July 1 Jenner inoculated the boy with matter from a case of smallpox. The inoculation was unsuccessful. Jenner drew up in 1797 a short treatise embodying his results, and it was presented unofficially to the President of the Royal Society (Sir Joseph Banks). Two manuscripts of this first draft are in existence—one in the Royal College of Surgeons and the other in the Wellcome Historical Museum. The paper was refused, and Jenner in the following spring added further material and published the work privately in July, 1798. The book bears the title: *An Inquiry into the Causes and Effects of the Variolae Vaccinae, a disease discovered in some of the Western Counties of England particularly Gloucestershire, and known by the name of the Cow Pox*. A second edition was published in 1800 and a third in 1801. The work was also translated into many languages.

After the publication of this work Jenner spent three months in London (1798) looking for volunteers for vaccination. In this he was quite unsuccessful. But he left in the hands of Henry Cline, the surgeon, the quill of dried lymph referred to above. Cline used it as a measure of counter-irritation in a case of hip disease, and found that the patient had become immune to inoculated smallpox. From this case the practice of vaccination began to spread. Very soon a difficulty arose, since Dr. Woodville had been distributing lymph derived from vaccinations carried out at the smallpox hospital, and not unnaturally it produced mild smallpox eruptions. Dr. Pearson, a fashionable physician, had taken up vaccination enthusiastically, and in 1800 he proposed to establish an institution for gratuitous vaccination. Jenner was offered the post of "Extra Consulting Physician." From this and other incidents it was apparent that Pearson was trying to filch from Jenner the credit for the discovery. But events such as these could not rob him of the many honours which soon came to him, and which he received modestly but with due appreciation. Jenner spent some time in London in 1800, and he was then requested to vaccinate the 85th regiment, which he did personally.

About the same time the practice spread to the United States, where Professor Benjamin Waterhouse was largely instrumental in obtaining results. France, Spain, and the Mediterranean countries soon followed.

Jenner's Later Life

Vaccination was now becoming an established practice throughout the world, and Jenner was kept busy with a very voluminous correspondence. There is no doubt that his practice and his affairs had suffered as a result of his devotion to the cause which he had made. His friends advised him to petition Parliament for a grant, and in 1802, after a thorough inquiry, he was voted a sum of £10,000. In the following year he presided at the annual meeting of the Royal Jennerian Society, but a few years later its affairs were found unsatisfactory, and it was replaced by the National Vaccine Establishment. For a brief period he took a house in London and carried on a London practice. In 1806 Parliament again considered his case, voting him a sum of £20,000. Between that date and 1815, when his wife died, he resided at Berkeley and at Cheltenham. He now settled finally at Chantry Cottage, Berkeley—in which so much of his work had been done—and there he died on Jan. 26, 1823.

Epilogue

Jenner was indisputably the "discoverer of vaccination"—the promoter of the deliberate practice which he had been the first to envisage and to carry out. It is true that his *Inquiry* is a record of a very small number of cases and even fewer deliberate experiments. But an investigation must be judged by its results. The *Inquiry* led almost immediately to far more experiments in many countries than a regiment of individual investigators could have undertaken. When once the practice had been launched Jenner helped it forward in every possible way. He personally vaccinated individuals almost daily; in the early stages he attended meetings, and helped by interviews with all those in authority who could further his end—the abolition of smallpox. From 1798 until his death he carried on an extensive correspondence with scientists and physicians in many lands.

It may be considered a tragedy that Jenner in his first book maintained that cowpoxing—if properly carried out

urine, with a delay of 15 minutes before adding the acetate solution.

(v) The addition of hydrochloric acid of analytical quality, 2.5 ml. of 22% aqueous solution to 2.5 ml. of urine. Hydrochloric acid of this standard of purity is subsequently referred to in the text as hydrochloric acid A.R.

(vi) The addition of hydrochloric acid, corresponding in quality to the standards laid down in the *British Pharmacopoeia*, in the same concentration and proportions as in test v. Hydrochloric acid of this standard of purity is subsequently referred to in the text as hydrochloric acid B.P.

(vii) The addition of hydrochloric acid of analytical quality as in test v, together with small amounts of an oxidizing agent, hydrogen peroxide.

All the aldehyde reagents used were made up with reagents of analytical quality. In tests v, vi, and vii large amounts of hydrochloric acid were used (actually equal to the amount in Watson's test), as it was thought that colour reactions due to substances other than urobilinogen would be more likely to appear at this high level of acidity. It is well known that the pigment produced by the urobilinogen-aldehyde reaction is soluble in chloroform. Accordingly, all the specimens were extracted with chloroform after submission to the tests described. A total of 5,600 tests were carried out on the 100 urines. The results are shown in Table IV.

A study of Table IV indicates the following points:

1. Out of the 100 urines tested 29 gave colour reactions of varying hues with Ehrlich's rosindole reagent; Savory and Moore's reagent, or Watson's test. A pink or red colour, however, was obtained in only 16 urines.
2. Colour reactions with all aldehyde reagents were more readily demonstrated at 35° C. than at room temperature.
3. Colour reactions with aldehyde reagents were more readily demonstrated in fresh than in old urines.
4. Delay in addition of acetate to specimens tested with Watson's reagent resulted in a considerable increase in the appearance of colouring substances insoluble in chloroform. This phenomenon was noted by Kelly *et al.* (1946). It was obviously due to colour reactions induced by the large amount of hydrochloric acid present in Watson's reagent which had not been neutralized until 15 minutes later.
5. Substances giving colour reactions with hydrochloric acid alone were more readily demonstrated in warm urines than in cold urines, and this applied both to fresh and to old specimens.
6. Of the 100 urines tested at room temperature with 22% hydrochloric acid A.R., 9 specimens gave a pink colour not extracted by chloroform, whereas when the same urines were tested under the same conditions with hydrochloric acid B.P. 69 gave a pink colour not extracted by chloroform. A similar high incidence of colour changes was noted when hydrochloric acid A.R. was added to the urines in the presence of a small quantity of hydrogen peroxide. From this it may be assumed that the principal impurity in hydrochloric acid B.P. leading to colour reactions is an oxidizing agent, and indicates the essential need for using hydrochloric acid A.R. in making up the Ehrlich aldehyde reagent. The substance which gives rise to a pink or red colour following the addition of impure hydrochloric acid to urine, and which is insoluble in chloroform, is believed to be an indole derivative, uroresoin (Meiklejohn, 1948—personal communication). The production of uroresoin depends both on the presence of an oxidizing agent and on the strength and quantity of hydrochloric acid used in the test. The high incidence of chloroform-insoluble pink substances observed when the addition of acetate was delayed in Watson's aldehyde test can possibly be explained on this basis.

In a previous investigation of the Ehrlich aldehyde test a different series of 45 urines had been tested with the rosindole reagent. Twenty positive colour reactions were recorded, and in six instances the colour observed, although macroscopically indistinguishable from that produced by urobilinogen, was not extracted by chloroform. Thus in

one-third of cases this reagent gave false positive results. On inquiry it was found that hydrochloric acid B.P. had been used in making up the reagent, as no instructions had been given to use analytical reagent. When the tests were repeated with rosindole reagent containing hydrochloric acid A.R. no colouring substances that were insoluble in chloroform were obtained.

Terwen (1925) and Watson (1931, 1936) have pointed out that the rapid conversion of hydrochloric acid to acetic acid by the addition of sodium acetate inhibits colour reactions due to indole. This procedure apparently also inhibits colour reactions due to indirubin. Thus when Watson's test is carried out the only important substances apart from porphobilinogen contributing to colour reactions are unidentified compounds having in general the same clinical significance as urobilinogen. The 15 urines which had given pink or red colour substances soluble in chloroform with rosindole reagent and Savory and Moore's reagent were accordingly submitted to the following procedure: 0.5 ml. of Savory and Moore's reagent was mixed with 5 ml. of urine followed immediately by 1 ml. of a saturated aqueous solution of sodium acetate. If a red or reddish-pink colour developed urobilinogen was considered present in an abnormal amount. In two of the 15 urines the colour reaction was inhibited and therefore the pink colour originally observed in these specimens was due to substances other than urobilinogen. In both instances the colour reactions had been only weakly positive, the colour change in one being perceptible only at 35° C., and in the other after several minutes at room temperature and at 35° C. This would suggest that weak delayed colour reactions with aldehyde reagents should be discarded as negative. The suggested lowest criterion of positivity is the development of a definite reddish-pink colour within five minutes at room temperature or within one minute at 35° C.

TABLE V.—A Comparison of Typical Colour Reactions Obtained from 100 Urines with the three Aldehyde Reagents Tested

Reagent	Temperature	Positive Results	Urobilinogen Proved Present	False Positive Results
Rosindole ..	14–18° C.	10	9	1
	35° C.	15	13	2
Savory and Moore's	14–18° C.	10	9	1
	35° C.	15	13	2
Watson's ..	14–18° C.	6	6	0
	35° C.	8	8	0

Table V gives results which enable the sensitivity of the three tests to be compared. It shows that tests with Ehrlich's rosindole reagent and Savory and Moore's reagent are more sensitive, although less specific, than Watson's test when read by the naked eye. The reduced sensitivity in Watson's test must be due in part to the threefold dilution of the urine with reagents.

The substances which are most likely to give rise to a reddish-pink colour when urine is tested with Ehrlich's aldehyde reagent are urobilinogen, indole, the precursors of two indole pigments—indirubin and uroresoin—and porphobilinogen. Uroresoin and porphobilinogen-aldehyde are insoluble in chloroform. The other pigments produced are soluble in chloroform. If the hydrochloric acid employed in the reagent is pure and free from oxidizing agents, and the reagent is used in small amounts, or if, as in Watson's test, the acid is immediately neutralized with sodium acetate, the reddish-pink colour developing in urine is unlikely to be due to any substance other than urobilinogen. Since, however, it is never possible to be certain that excessive amounts of hydrochloric acid or impure acid have not been used in making up the aldehyde reagent, and since the latter may become contaminated

oxidizing substances, it is essential that the red or pink colour developing in the test should invariably be submitted to chloroform extraction. By this means the most important single fallacy—namely, a pink colour to urochrome—can be excluded. If it is suspected that a substance giving rise to a pink colour soluble in chloroform is not urobilinogen (an exceptional finding if the reagents are properly prepared and if very weak delayed reactions are disregarded), then a saturated solution of sodium acetate should be added immediately after the aldehyde reagent to ensure the specificity of the test.

Conclusions

Ehrlich's aldehyde test is a simple and valuable clinical procedure for the detection of abnormal amounts of urobilinogen in the urine. The reaction is more sensitive if the urine is tested in the fresh and warm state.

The following precautions should be rigidly observed. The hydrochloric acid in the test reagent should be analytical standard and used in appropriate amount. The reagent should be put out for use in small droplets, and contamination with pipettes, etc., should be avoided. (3) The reaction should be considered negative only if a definite reddish-pink colour develops within five minutes at room temperature or within one minute at 37°C. (4) Chloroform extraction should be undertaken only if the urine giving a red or reddish-pink colour subsequent to the addition of aldehyde reagent. (5) Sodium acetate solution should be added immediately after the addition of Watson's reagent if Watson's test is employed. Addition of sodium acetate is unnecessary if Savory's reagent is employed in the amount used in the experiments. (6) The reagent should not contain indole, as this is unnecessary and more likely to produce positive results with indole.

Further work is required to determine the optimal quantity of paradimethylaminobenzaldehyde and hydrochloric acid to be included in reagents used for qualitative estimation of urobilinogen and the relative amounts of reagent in urine to be employed in the test. Having been determined, these quantities should be strictly adhered to, as by so doing the inhibition of specific urobilinogen colour reactions and the production of colour reactions due to indoles and other unknown substances will be reduced to a minimum.

The Minister of Health has decided, after consultation with the Central National Health Service (Chemist-Contractors) Committee, that the use by contractors of envelopes or other paper containers for tablets, pills, capsules, pastilles, lozenges, and for bulk powders is desirable, and that they should not be used for this purpose after 1.1.1949. The British Standards Institution is considering minimum standard requirements for cardboard or paperboard containers until the inclusion in the Drug Tariff of a reference to these requirements, boxes used for a small number of tablets, pills, etc., must be large enough to bear a label on which the directions can be clearly shown.

RETENTION OF URINE*

By

E. W. RICHES, M.C., M.S., F.R.C.S.

Surgeon and Urologist to the Middlesex Hospital

Among the many possible causes of inability to pass urine prostatic obstruction is the most frequent in everyday practice. Paralytic or neurogenic causes occupy second place, and stricture nowadays comes third because its principal cause, gonorrhoea, is more effectively treated. Retention from prostatic obstruction can be taken as the example for description, but the same principles of treatment are applicable to other cases.

Retention implies a full bladder from which either nothing can be passed, as in acute retention, or only a dribbling overflow escapes, leaving a large amount of residual urine, as in chronic retention. It must be distinguished from the more serious condition of suppression of urine in which the bladder is empty. It is therefore necessary at the outset to be able to recognize a full bladder, and to do it without having to pass a catheter, the method recommended in some gynaecological textbooks. It is generally easy by ordinary clinical methods. There is a rounded or irregular swelling arising from the pelvis, fixed below, dull on percussion, cystic, either tense or soft, and sometimes translucent from side to side. In cases of doubt examination with the foot of the bed raised will occasionally make it more evident. Sometimes, however, there are difficulties, especially in a fat patient, and particularly where there are no urinary complaints and the condition is not suspected.

A man of 64 went to his doctor complaining of general ill-health, with loss of weight, morning vomiting, and loss of taste. He had no urinary symptoms and did not have to get up at night to micturate. He was sent for a complete barium-meal examination, and the radiologist discovered a pelvic tumour, outside the bowel but pushing it up. The tumour was an enlarged bladder. The prostate was moderately enlarged and the blood urea was 84 mg per 100 ml. The urine having a specific gravity of 1002. After the bladder had been gradually decompressed through a small suprapubic catheter his symptoms ceased, the blood urea fell to 30 mg per 100 ml, and after prostatectomy he recovered.

Clinical Types of Retention

Acute Retention.—There is often no sharp dividing-line between acute and chronic retention, and while the amount of residual urine is generally large in chronic retention this factor alone does not give a complete definition. Acute retention is of sudden onset and is painful. It follows congestion and is brought about by cold, wet, and alcoholic, dietary, or sexual excess. Brodie in 1822 said: "The exciting cause is sometimes cold. One gentleman will be affected after drinking punch, another after drinking more wine than usual. One gentleman I knew was seized after two or three days' costiveness. The cause is often too minute to be detected." Other potent causes of acute retention are enforced holding of urine when the call comes and confinement to bed for some intercurrent disease such as bronchitis, pneumonia, or heart failure. A painful acute retention may be superimposed on a degree of chronic retention. The clinical picture of acute retention is unmistakable: there is a constant urge to micturate, but inability to expel more than a few bloody drops, with severe pain in the penis and lower abdomen, restless changes

*Based on a lecture given to the Leeds Branch of the British Medical Association on Feb. 9.

of posture, sweating, and apprehension. The relief when the bladder is emptied is dramatic.

Chronic Retention.—By contrast chronic retention is relatively painless, although there is sometimes a history of loin pain, and the patient may have no idea that he has an abdominal swelling. The term "chronic" denotes that the condition has been present for a long time; the bladder has become gradually distended and is decompensated; it can be detected on clinical examination, and other symptoms such as have been mentioned will probably be present; loss of weight and alteration in the sense of taste are frequent signs of uraemia. Chronic retention is the more dangerous state of the two.

Treatment of Acute Retention

From the general practitioner's point of view the treatment of acute retention consists in relieving the pain of retention and sending the patient into hospital. The retention, and the consequent pain, can be relieved in more than one way.

A hot bath and a morphine suppository ($\frac{1}{2}$ gr.—32 mg.).—This is not always possible, and is seldom successful in prostatic cases. It is more likely to succeed in retention from stricture, where the congestive element plays a large part.

Catheter.—This is the time-honoured method, and it is still correct provided that gentleness and strict asepsis are maintained. A gum-elastic bicoudé catheter is more likely to pass easily than a soft rubber one; the silver prostatic catheter should not be used. A fairly stiff rubber catheter of the Tiemann type is effective, and it can be boiled.

Aspiration.—A serum or lumbar-puncture needle is inserted under local analgesia through the abdominal wall into the bladder and the urine withdrawn by a syringe. The needle

FIG 1.—In emptying a distended bladder by aspiration the needle is directed downwards and backwards

should be inserted well above the symphysis pubis and should be directed obliquely downwards and backwards (Fig. 1). This procedure can be repeated if absolutely necessary, but the needle should be inserted in a slightly different spot and the bladder should not be allowed to fill up as much as before. Aspiration is less likely to introduce infection than is the passage of a catheter. The danger lies in repeated catheterization, and even when sulphonamides are given, as they should be, catheterization under home conditions is almost certainly followed by infection if continued for more than two days. An indwelling catheter increases the certainty of infection, which in a closed bladder may cost the patient his life.

Carbachol is unlikely to relieve retention when there is mechanical obstruction.

After the relief of acute retention micturition approaching the normal may be re-established, but the patient should still be sent into hospital. One attack of acute retention is the precursor of others and is an indication for prostatectomy before the condition becomes chronic. If micturition is not re-established the condition is more urgent and the man who has had repeated catheterization becomes a bad subject for prostatectomy.

Treatment of Chronic Retention

It is of fundamental importance to realize that the bladder should not be emptied just because it is found to be full.

Although it may be done with impunity on many occasions, there is always the risk of producing renal haematuria and suppression of urine, even if infection is not introduced. The patient should be sent into hospital without undue delay; the condition has probably been present for some time, and a day or two more may make little difference, but the sooner treatment is instituted the better. Under proper surroundings the surgeon is faced with the decision of draining the bladder first or of doing an "immediate" prostatectomy after a minimum of time in assessing renal function and preparing the patient. The important principles to be followed in drainage are to avoid sudden decompression, to avoid urethral trauma, to prevent infection, especially ascending infection, and to plan ahead. I am a firm believer in preliminary drainage in chronic cases provided it is carried out in such a way as not to prejudice the subsequent prostatectomy.

There has recently been a tendency to make light of the dangers of sudden emptying of the bladder in chronic retention, but cases of suppression of urine from this cause still appear only too often. If there is hydronephrosis and hydroureter the release of pressure affects the upper urinary tract as well as the lower. The renal blood vessels have become adapted to an increase of pressure, and when it is suddenly released intrarenal haemorrhage may follow, leading to tubular blocking.

Preliminary decompression and drainage may be carried out by urethral catheter, by urethrostomy, by suprapubic cystostomy, or by suprapubic catheterization.

Urethral Catheter

This is the simplest method of drainage and allows of slow decompression. If it could be forecast with certainty that it would not be required for more than two days it would be relatively safe. A rapid estimation of renal function is necessary before it is used; the blood urea figure does not show minor degrees of renal impairment, but a high value—for example, over 80 mg. per 100 ml.—is an indication of renal damage and generally means that a longer period of drainage will be necessary before prostatectomy. A persistent specific gravity of the urine of about 1010 is also an index of severe renal insufficiency. These are the tests of most practical value when time is a factor. Even a short period of catheterization, however, is followed by urethritis, and this may lead to prostatitis, cystitis, and finally to pyelonephritis from ascending lymphatic infection.

Wilson Hey (1945), who has done so much to make urologists conscious of the dangers of infection, is opposed to any form of urethral instrumentation before prostatectomy. The added danger of urethral trauma is also present. If a urethral catheter is used it must be of good rubber and must be small enough to allow of free drainage around it; even a catheter of suitable size may produce a meatal stricture.

Urethrostomy

Sandr y (1949) has drawn attention to the value of drainage by a catheter inserted from the bulb of the urethra, and finds great advantages in the dependent drainage achieved over the uphill drainage of suprapubic cystostomy. In a series of 58 poor-risk cases there was a mortality of 8.6% and there were no deaths from urinary infection. The method has obvious advantages, but it still leaves one-third of the urethra exposed to the friction of a catheter. It is not so easy to keep the patient ambulant—an important feature during the period of drainage—and there is a leak lasting from four to five days after removal of the catheter. There are also possible nursing difficulties.

Suprapubic Cystostomy

While drainage is effective, the decompression by operation is not always gradual. The main disadvantages, however, are in the frequent leakage around the catheter and in scarring of the operation field for the prostatectomy; this especially so when the tube is placed low on the abdominal wall, as is so often the case. The low suprapubic tube, entering

just above the symphysis and passing horizontally into the bladder from the lower end of a long vertical incision, is something which should be banned from modern surgery. It leaks, it smells, and it makes a clean prostatectomy impossible (Fig. 2).

FIG. 2.—Low suprapubic cystostomy.

Suprapubic cystostomy as a first stage of prostatectomy has a high mortality. Rees (1947) reported 30 deaths in 106 cases so treated—a mortality of 28%, of which more than one-half were infective. He also recorded 18 deaths during gradual decompression by urethral catheter.

Suprapubic Catheterization

The method devised originally for cases of spinal injury with bladder paralysis (Riches, 1943) has now been used extensively for decompression and drainage of the bladder in chronic retention. A small rubber suprapubic catheter (16 F.) is inserted by a special trocar, the catheter itself acting as the cannula. It gives a watertight fit and can be advanced to the base of the bladder by an internally expanding advancer (Fig. 3). It is inserted obliquely downwards and backwards,

FIG. 3.—(a) The suprapubic catheter introducer. (b) The catheter stretched on the introducer. (c) The advancer.

starting from the highest point of bladder dullness or the mid-point between the umbilicus and the symphysis, whichever is the lower. If there is any doubt about the fullness of the bladder a small incision is made at the same point and the instrument and catheter are inserted under direct vision. The catheter is held in place by a loop stitch through the skin, the ends of which pass twice around the catheter (Fig. 4); a

FIG. 4.—Suprapubic catheter in position

small rubber shield held on by a strapping corset serves to retain a dressing around it and prevent movement. Kidd's U-tube has been found the most effective method of decompression, which is completed in 12 hours, after which the patient can get up if other conditions permit. The danger of injury to the peritoneum is minimal if the bladder is distended, as is the case when the operation is needed, and as an added safeguard the foot of the bed or operating table is raised during the insertion. When the bladder contains $\frac{1}{2}$ pint (425 ml.) there is usually a bare area devoid of peritoneum for 3 in. (7.5 cm.) above the symphysis.

This method fulfils all the suggested principles of treatment: decompression is slow; there is no urethral instrumentation; ascending infection is avoided, as there is no direct lymphatic pathway from the track of the catheter to the kidney; and the field for the second operation is left intact. It can be done safely under a local anaesthetic however ill the patient, it is leak-proof, and it can be prolonged as long as necessary. If the drainage has to be maintained for more than two weeks the catheter is changed on the fourteenth day. The old one is removed, and an open-end rubber catheter of the same or a larger size is immediately passed along the track. There must be no delay about this, as the fistula closes rapidly owing to its obliquity; after prostatectomy it closes spontaneously in a few hours, and it is exceptional for it to leak. There has been no apparent disadvantage from the "uphill" drainage, and the bladder urine has often remained sterile for a fortnight. Where renal function can recover it will do so, and the improvement in appetite and general well-being is often remarkable. The blood chemistry gives an indication of the need and type of intravenous fluids.

During the five years 1943-8 I have used this method for the drainage of chronic retention in prostatic obstruction in 227 cases; there were 12 deaths—a mortality of 5.2%—and none were from urinary infection. If three cases in which the drainage was purely palliative—in patients dying from heart failure or advanced carcinoma—are excluded the mortality was 4%, and if those who had never been catheterized or cystoscoped could be excluded it would be 2.6%. There will always be a mortality in dealing with these patients by whatever method, and it is remarkable how they get along so well until they are subjected to surgical intervention.

Immediate Prostatectomy

There is no doubt that the benefits of preliminary drainage have in the past made surgeons too cautious about prostatectomy in one stage: there are still those who practise a two-stage operation in every case. Their results in terms of mortality are excellent, but in playing for safety they lose many advantages. The modern dry prostatectomy, by whatever route, is a vastly different procedure from the two-stage Freyer from which it has developed. There need be no suprapubic leak, the patient can be up on the second day, and the convalescence is smooth and relatively painless. The horrors and discomforts of the older operations are still vividly recalled, and have made the operation one which men dread and in consequence defer until something has to be done.

The work of Wilson Hey (1945) in stressing the importance of asepsis has done much to reduce the number of two-stage operations. He himself advises a one-stage operation, following his own technique in every case, whether retention is acute or chronic; his figures are instructive, showing a total mortality of 6% in all cases. Where the blood urea was below 80 mg. per 100 ml. it was only 3.4%; with a value between 80 and 200 mg. it rose to 16.1%, and over 200 mg. it was four out of six cases (66.6%). It is evident that whilst a one-stage aseptic operation is applicable to many cases there are also a number of bad-risk cases that will not survive it. Some of these cases with chronic retention and considerable renal damage can be saved by preliminary drainage.

In one patient with a blood urea of 420 mg. per 100 ml. suprapubic catheterization with slow decompression brought it down to 38 mg. after eight weeks' drainage, and he came safely through a Harris prostatectomy and made a good recovery: I do not think he would have survived a one-stage operation. His wound was dry on the day after the suprapubic catheter was removed and his convalescence was both comfortable and uneventful. By contrast a man with a blood urea of only 20 mg. per 100 ml. but with a chronic retention of 46 oz. (1.3 litres) died from uraemia

on the ninth day after a one-stage prostatectomy (retro-pubic), with a blood urea of 300 mg. I am therefore not a convert to a universal one-stage operation although I practise it whenever it seems safe to do so.

In an uncomplicated case the convalescence after a retro-pubic prostatectomy (Millin, 1945), or a Harris operation with closure, or a Wilson Hey prostatectomy can be as uneventful as that after an interval appendicectomy, and the mortality should not exceed 5%. When there is chronic retention of urine or much renal damage or gross infection preliminary drainage will give the patient a better chance of survival. Drainage by the small suprapubic catheter has proved a safe and satisfactory method, and it does not interfere with the full exposure required for any of the modern methods of prostatectomy.

If endoscopic resection is to be done the presence of the suprapubic catheter makes the operation much simpler, as continuous lavage can be employed to keep the field clear of blood. Where intercurrent cardiac, pulmonary, or other disease makes a long period of drainage necessary it gives the greatest chance of getting the patient fit for operation. In cases of bladder paralysis it allows for adequate drainage during the critical period and does nothing to prevent the return of voluntary micturition or the establishment of automatic micturition. Its main advantages lie in the high insertion of the catheter, the oblique track, and the absence of leakage.

OGILVIE'S SYNDROME OF FALSE COLONIC OBSTRUCTION

A CASE WITH POST-MORTEM FINDINGS

BY

J. A. DUNLOP, M.B., F.R.C.S.

(From Chase Farm Hospital, Enfield, Middlesex)

A syndrome of large-bowel colic thought to be due to sympathetic deprivation was recently described by Sir Heneage Ogilvie (1948), with a report of two cases, including laparotomy findings but without the possibility of full confirmation of the suggested anatomical diagnosis by post-mortem examination. The case now reported had been operated on before the first description of Ogilvie's syndrome, and its striking similarity to the original two cases (particularly to Case 2) was immediately apparent. When the disease had run its inevitable and very short course a full and careful post-mortem examination was performed. This third case may therefore be considered worth recording.

Case Report

The patient, a tall lean fitter aged 56, had long suffered from constipation, but had otherwise been in good health and free from pain until three months before his admission to hospital. Since that time he had noticed that his constipation was becoming more and more stubborn, and he suffered repeated attacks of colicky lower abdominal pain without diarrhoea or vomiting. These symptoms became increasingly severe and were attended by a progressive loss of weight, which he could ill afford, until, after four days' absolute constipation and a day's vomiting, on Sept. 8, 1948, he was sent into hospital as a case of chronic large-bowel obstruction due to carcinoma, becoming acute.

Examination on admission showed a very thin, ill-looking man with an unhealthy muddy complexion, in obvious spas-

modic pain. The abdomen was not at all distended generally, and the wall relaxed normally. There was a tender fullness corresponding to a distended caecum and transverse colon, but no lumps could be made out through the abdominal or rectal walls. Peristaltic sounds were exaggerated. The only other significant positive finding was a small area of consolidation at the base of the left lung. The speech was slow, slurry, perhaps slightly dysarthric, but otherwise the nervous system seemed normal. This examination made it clear that any obstruction was not complete, and an enema produced a constipated result and flatus, with relief of pain. On the following days the symptoms recurred, and, although distension was never present and flatus was passed spontaneously, defaecation could be induced only by enemata.

Plain radiographs of the abdomen and chest showed some increase in normal colonic gas shadows not amounting to a picture of true obstruction, an area of collapse at the base of the left lung, and an enlarged lower mediastinal shadow, interpreted as being due to a primary or secondary neoplasm obstructing the left lower bronchus, with secondary mediastinal glands. After some days in hospital the patient complained of dysphagia, which he said had been present for a few weeks, but very mildly, and was now becoming more noticeable. A barium swallow and x-ray screening showed some hold-up in the lower thoracic oesophagus, again thought to be due to a mediastinal new growth.

Follow-up of this barium seemed to indicate a complete hold-up in the pelvic colon, with gross colonic distension proximally. However, on further screening the radiologist reported that he did not think there was an organic obstruction at this level, and suggested a barium enema. Meanwhile the general condition and the morale of the patient were deteriorating, the severe pains continued, the bowels remained immovable, and there were repeated requests for any operation which offered a chance of relieving his symptoms. It was felt that even with a negative barium enema laparotomy would eventually be forced by these facts, although, in view of the chest condition, at best a very temporary palliation was all that could be hoped for.

Laparotomy was performed on Sept. 21 through a midline incision. Below the level of the gastro-hepatic omentum the whole abdomen was normal. The colon showed neither distension nor spasm. The liver was studded with secondary growths, and an apparently carcinomatous mass was palpable in the pre-aortic region about the level of the coeliac axis. A small piece of liver secondary was excised for microscopy and the abdomen closed. After operation the patient became more and more cachectic, a terminal chest infection appeared, and he died on Oct. 21, one month after operation.

Post-mortem Examination.—The primary lesion was found to be an extensive carcinoma of the left lower bronchus, with secondary glands in the mediastinum invading the oesophagus, a large secondary in the right lobe of the thyroid, multiple secondaries in the liver, and some secondaries in the pre-aortic region. The apex of the left and base of the right lung showed an acute tuberculous process, which presumably had hastened the end. Microscopically the growth was highly anaplastic, and consisted of sheets and cords of spherical cells with round pyknotic nuclei and very little cytoplasm. The splanchnic nerves were very carefully dissected throughout, and were found to be entirely free from any involvement in growth in their pre-ganglionic course. On tracing down the connexions of the semi-lunar ganglion distally the mat of efferent nerve fibres leaving the left side of the ganglion passed direct into a carcinomatous mass, presumably deriving from an affected pre-aortic gland. After fixation this relation was even more striking and definite. The left vagus was probably involved by growth in the thorax, although visible as a normal nerve uninvolved by carcinoma below this level; the right was uninvolved throughout its course. The brain and meninges were normal.

Discussion

The similarity of this case to those in the original description needs no emphasis. After laparotomy in my case two explanations seemed possible: (1) colonic muscle imbalance caused by interruption of sympathetic pathways (stated thus vaguely, with none of Sir Heneage's precision), or (2) that

suggested by Cushing's demonstration of acute peptic ulcer due to spasmodic and incoordinated contractions of stomach muscle in the presence of vagal overaction and sympathetic paralysis caused by lesions in the hypothalamic region (Cushing, quoted by Bockus, 1944). In view of the suggestion of dysarthria, it was thought that cerebral secondaries might be present, one of which could be causing a similar disturbance of colonic innervation and function. This explanation disposes of the difficulty about sympathetic afferents mentioned by Ogilvie, and may be thought to remain a theoretical possibility. The lesion actually demonstrated bears out Ogilvie's speculations about causation very accurately, including his forecast of its post-ganglionic position, where the fibres are non-medullated and presumably more vulnerable. Clearly the syndrome can occur only where efferent sympathetics are affected and afferents spared. This fact perhaps accounts for its rarity, while malignant disease of coeliac and pre-aortic glands is all too common.

In the absence of post-mortem findings the original description suggested that the dysfunction lay in the left colon. The symptoms irresistibly suggest a lesion of the left colon by analogy with those of an obstructing cancer of that organ. But if the wasting, distension, colic, and constipation are not due to organic obstruction, they may as easily originate in the mid-gut as in the hind-gut. That in fact they do is suggested by the following points.

(1) The sympathetics demonstrably affected were the splanchnics; these supply the bowel nourished by the superior mesenteric artery. (2) A subdiaphragmatic lesion of the ganglionated sympathetic chain denervating the left colon should also denervate and cause vasodilatation in the left leg (Telford, 1948). This effect is not recorded in any of the extant cases. But none of the cases had any carcinoma sufficiently distal to interfere with the "lumbar splanchnics" or the inferior mesenteric plexus—i.e., the left colon's sympathetic supply after leaving the chain. Thus a sympathetic denervation of the left colon seems anatomically very unlikely. (3) In the present case a radiograph taken 48 hours after a barium swallow showed a colon dilated up to the splenic flexure (the lower limit of the mid-gut) and normal or spastic thereafter, and gross dilatation of a small-bowel loop in the position of the terminal ileum. The plain radiograph taken on admission shows substantially the same picture.

It seems certain, therefore, that in this case the dysfunction involved the lower ileum and proximal colon, and it is probable that this will be found to be a general rule.

If it is objected that sympathetic deprivation should cause spasm, not dilatation, it can be argued thus: (1) That, since all these cases were characterized by colic, spasm obviously occurs: the bowel is normally a rhythmic organ, and abnormal diastole may follow abnormal systole. (2) That the physiology of the human bowel's response to autonomic stimuli is still obscure, and its response to deprivation of its sympathetic efferents while retaining sympathetic afferents much more so. (3) That, in this case, it is an experimental fact that a gross lesion of the sympathetic efferents to the mid-gut, in the presence of at least an intact right vagus, was followed by dilatation of the distal part of the mid-gut. (4) That more accurate study of further cases is needed before any final conclusion is possible.

Summary

A third case of Ogilvie's false large-bowel-obstruction syndrome is presented in which the primary lesion was a carcinoma of bronchus and there was post-mortem proof of carcinomatous infiltration of sympathetic post-ganglionic fibres below the semilunar ganglion. An alternative theory of causation of the syndrome is postulated, but it was proved incorrect

in this case. Evidence suggests that the lesion affects the mid-gut rather than the hind-gut.

My thanks are due to Mr. H. O. Blauvelt for permission to publish this case, to Dr. Doel for the radiological opinions, and to Dr. Prendiville for the post-mortem and pathological findings.

CHRONIC ILEUS CAUSED BY MALIGNANT INVASION OF THE POSTERIOR ABDOMINAL WALL

BY

R. S. HANDLEY, M.B., F.R.C.S.

Assistant Surgeon, Middlesex Hospital; Surgeon, Bolingbroke Hospital

Sir Heneage Ogilvie (1948) has described, under the title "Large-intestine Colic due to Sympathetic Deprivation: A New Clinical Syndrome," two cases in which invasion of the crura of the diaphragm, coeliac axis, and semilunar ganglia by malignant growth produced a functional paralysis of the bowel which mimicked obstruction. The following case history reports invasion of the same area by what was probably a carcinoma of the pancreas, producing symptoms which suggested obstruction of the small intestine.

Case Report

The patient, a man aged 56, had suffered from mild dyspepsia all his life. His appendix was removed in 1936. A barium meal in 1943 had shown a scarred duodenal cap. Apart from occasional discomfort after food and a tendency to vomit if he was mentally disturbed, he had been healthy until two months before he visited me. He had then begun to suffer from attacks of colicky pain centred around the umbilicus, with tenderness in the right iliac fossa. The attacks came every few days, lasted a few hours, and left a sensation of abdominal distension. These attacks had become more frequent during the past fortnight and he had vomited every other day. A barium meal had shown a normal stomach and duodenum, and a barium enema a normal colon. He had lost half a stone (3.18 kg.) in weight. There had been no constipation except during the past week. His own doctor had thought he could feel a vague mass to the right of the umbilicus. While the history was being taken borborygmi were audible.

Examination showed a right paramedian appendicectomy scar, tender in the centre, and slight abdominal distension; borborygmi were well heard without a stethoscope, but there was no visible peristalsis or other abnormality. The remainder of the physical examination was negative. A provisional diagnosis of subacute intestinal obstruction due to adhesion of a segment of terminal ileum to the back of the paramedian scar was made, and operation was advised.

The patient was admitted to a nursing-home and a small barium meal requested with the object of locating the point of obstruction in the small intestine. Dr. T. V. Crichton reported on the screening examinations and films as follows: "At three hours there are some coils of dilated small gut in the left hypochondrium and left iliac fossa. The mucosa is swollen and the calibre of the gut enlarged. In the right iliac fossa there is one loop of gut which appears to be contracted. At five hours there is still some dilatation of the loop seen at three hours, but there is no adherent portion to be seen. At eight hours this loop is completely empty, but the terminal ileum in the region of the ileo-caecal valve and also in the region of the hepatic flexure shows a moderate degree of enlargement. There is a fair amount of delay in the passage of the barium through these loops. At twelve hours the barium is completely in the colon. *Conclusions*.—There is definite

evidence of enlargement of some of the coils of the small gut, probably involving only the ileum. The appearances are consistent with partial obstruction such as could be produced by adhesions. No definite filling defect was seen in the lumen of the small gut."

Operation (anaesthetist, Dr. O. Carden Sibley; gas, oxygen, ether).—At laparotomy the small intestine was seen to be moderately distended but no obstruction was found. Hard glands were palpable in the upper part of the mesentery of the small intestine and a growth was found in the body of the pancreas, spanning the aorta, fixed to the posterior abdominal wall and quite irremovable. The large intestine was of normal size. A gland was taken for section and the abdomen was closed.

The patient became progressively distended after the operation despite gastric suction and intravenous glucose and saline, partly burst his wound, and died on the fourth post-operative day. No necropsy was obtained, but the gland removed at operation showed replacement by masses of undifferentiated carcinoma.

Discussion

A somewhat cursory search of the literature shortly after the patient had died, and discussion with colleagues, failed to throw any light on the matter. Ogilvie, who likewise failed to find any reference to the subject in the literature, appears to be the first to publish a description of this unusual syndrome. The manner of its production is of great but academic interest, since the symptoms are produced only after inextricable invasion by carcinoma of a relatively inaccessible region of the body. Ogilvie considers three methods by which the symptoms might be produced: (1) by parasympathetic stimulation from invasion by the tumour; (2) by secretion of a cholinergic substance by the tumour cells; or (3) by sympathetic paresis from invasion by the tumour. He believes, despite some contrary points, that the last is the probable explanation.

A fourth explanation might be considered in my case—that interference with the blood supply by pressure of the tumour on the superior mesenteric vessels might have evoked the symptoms. Mesenteric thrombosis will cause colic, borborygmi, and distension, though the picture is more acute. Against this theory is the fact that my patient's intestine showed no cyanosis. In Ogilvie's first case there was evidence that the pelvic colon was greatly affected, though the tumour cannot have caused interference with the inferior mesenteric artery. It seems, therefore, that the vascular hypothesis must fall down.

A carefully detailed post-mortem examination of a similar case might clear up the mystery, and it is to be hoped that it will be forthcoming.

REFERENCE

Ogilvie, W. H. (1948). *British Medical Journal*, 2, 671.

A six-months training course for hospital records' officers is being jointly run until about the end of July by the Association of Medical Records Officers, the King Edward's Hospital Fund for London, and the Board of Governors of the Middlesex Hospital. It is hoped that similar courses will be organized later. The Ministry of Health states that the Minister welcomes the growing interest of hospitals in the proper maintenance and organization of patients' records and the decision of many of them to overhaul their records systems and appoint designated records officers. If this development is not to go astray only adequately trained or experienced officers should be appointed; and boards and committees thinking of making such appointments should defer doing so, unless there are exceptional reasons for immediate action, until there are enough really suitable candidates. Some boards and committees may be considering buying more or less elaborate equipment, such as punched card machinery, for their records departments. The Minister appreciates the value of such equipment where the volume of work makes it an economic proposition, but he is advised that the circumstances of a single hospital, or even in many instances of a management committee group, do not normally justify its purchase. No steps of this kind should therefore be taken by management committees without consultation with the regional hospital board.

THIOURACIL IN THYROTOXICOSIS

BY

D. VÉREL, M.D., M.R.C.P.

(From the Department of Medicine, University of Aberdeen)

In this department 62 patients with thyrotoxicosis have been under treatment with thiouracil or methyl thiouracil for periods between 6 months and 4½ years. The series includes all cases of thyrotoxicosis admitted to the ward except a few so mild that phenobarbitone alone was used in treatment. The general results of treatment are here briefly recorded, and certain aspects of management in relation to auricular fibrillation, pregnancy, and granulopenia are discussed in the light of the experience gained.

Particulars of a Series of Cases

The distribution of cases by age, sex, and the presence or absence of exophthalmos is shown in Table I. Ten of the patients were males and 52 were females; their ages varied from 16 to 66 years. Exophthalmos was more common among the younger patients. No attempt was made to differentiate between primary and secondary thyrotoxicosis, and in only one case was there a definite history of an enlargement of the thyroid preceding the thyrotoxicosis by several years.

TABLE I

Age:	10-19		20-29		30-39		40-49		50-59		60-69	
Sex:	M	F	M	F	M	F	M	F	M	F	M	F
Eyes No.	E	O	F	O	E	O	E	O	E	O	E	O
	1	2	1	2	0	6	1	2	5	3	1	2
	1	2	1	2	0	6	1	2	5	3	1	2

E = Exophthalmos present. O = No exophthalmos present.

All cases were admitted to the ward for treatment, and the effect of rest in bed and 1 gr. (65 mg.) of phenobarbitone three times a day was observed for one to three weeks. When the sleeping pulse had settled to a constant level for several nights, and the patient's symptoms showed no tendency to abate further on this treatment, the basal metabolic rate was estimated with the Benedict-Roth apparatus on two successive mornings, and treatment with thiouracil or methyl thiouracil was begun. The dose of thiouracil used at first was 0.6 g. daily, and this proved effective in all cases. Later 0.2 g. was tried, but, while this would control thyrotoxicosis of mild or moderate degree, it failed to do so in two severe cases. It was found, however, that 0.4 g. of thiouracil daily was as effective an initial dose as 0.6 g. Methyl thiouracil proved equally satisfactory in doses of 0.2 g. daily, and is now used for all cases. Each patient's progress was followed clinically and assessed every ten days, when the basal metabolic rate was estimated. After three weeks on thiouracil the patient was usually discharged on a maintenance dose of 0.2 g. of thiouracil or 0.1 g. of methyl thiouracil daily, and was seen thereafter at intervals of six weeks. White cell counts were done twice a week in hospital, and at each out-patient attendance, although it was realized that they were of no value as indicators of impending agranulocytosis. They served to remind the patients of the possible dangers of the treatment, which had been explained to them in the ward, and revealed several cases of granulopenia.

Most cases were adequately controlled by 0.1 g. of methyl thiouracil daily or less; some required 0.15 g. The dose was decided on a clinical estimate of the patients' condition when they reported to the follow-up clinic. No single observation was found to be completely trustworthy, but a reasonably accurate idea of the state of the patients was obtained by asking them how they felt, how much

work they could comfortably do, and whether they got any palpitations, also by noting the weight, resting pulse rate, state of the skin, and presence or absence of tremor. The size of the thyroid gland was also noted.

Thiouracil effectively controlled the thyrotoxicosis in all cases, and the majority were back in full employment within six weeks of starting treatment. All patients were old that they should regard themselves as restored completely to normal as a result of the treatment, and only two of the 59 cases given thiouracil alone have not returned to full activity. One is a woman with advanced spondylitis ankylopoietica who cannot do heavy housework, and the other a country postman who could not continue his bicycle deliveries. He is now working as a taxi driver. Most of the patients are housewives, and all except a few over 60 do their own housework, including scrubbing and polishing floors. Four are crofters' wives and had returned to full activity within six weeks of starting thiouracil, as had two men in very heavy employment—one a cyclist messenger, and one who does a full day's work shovelling granite into a crusher. A railway-track-layer was doing light work in four weeks and full work in eight weeks after starting thiouracil. The two patients still at school also lead normal lives without any restrictions.

TABLE II—*The Position in 1948*

Duration of Treatment (Months)	Group 1	Group 2	Group 3	Group 4	Total
6-12	2	7	0	0	9
2-18	9	3	0	0	12
18-24	5	3	1	0	9
24-30	4	7	0	0	11
30-36	2	1	0	0	3
36-42	2	2	0	0	4
42-48	3	0	0	0	3
48-54	2	0	0	1	3
54-60	2	0	0	0	2
Totals	33	23	2	1	59

- Group 1 Off thiouracil for three months or more and satisfactory
 Group 2 On thiouracil and satisfactory
 Group 3 On thiouracil and unsatisfactory
 Group 4 Off thiouracil and unsatisfactory

The position of the cases in the series in June, 1948, is shown in Table II. Of 13 patients who have been under observation for three years or more, five have taken no thiouracil for 33 to 39 months and have not relapsed, three have taken none for 21 to 31 months, three relapsed off thiouracil, two of them again being controlled by thiouracil and two have been taken off thiouracil within the last six months. Three patients are classified as unsatisfactory. (1) The patient off thiouracil is the only one in the series who developed a granulopenia with infection. She refused operation, and although living a normal life looking after her family, is moderately thyrotoxic. (2) This patient is adequately controlled by thiouracil, but has many symptoms caused by her life being spent in three rooms with her husband, two children, and her mother-in-law. (3) This patient feels well and does all her own housework, but has persistent tachycardia and appears to be slightly toxic. She states that visiting the hospital always makes her nervous.

Three cases are not included in Table II, and are accounted for as follows. One man aged 23 died of suppurative bronchiectasis. His thyrotoxicosis was under control at the time of death. Thyroidectomy has been performed on the other two patients. One of these was a man aged 30 who had previously been treated by deep x-ray therapy for polycythæmia rubra vera and developed a persistent granulopenia on thiouracil. Before thyroidectomy, when taking thiouracil, he was fit and doing full outdoor work as a gas-meter inspector. Now, fifteen months after thyroidectomy, he feels fit, but can only do

clerical work indoors, and is easily made breathless by exertion. In addition, the fine tremor of the fingers has returned, the skin is silken and sweaty, and there is a slight increase in the pulse rate, which, however, was never reduced below 90 per minute by thiouracil. The basal metabolic rate is 95% of normal. In the other case thyroidectomy was performed because of the great increase in the size of the thyroid.

Size of Thyroid

The size of the thyroid was estimated at each visit by inspection and palpation. Four categories were made: slight enlargement, when there was no visible goitre; slight to moderate enlargement, when the enlargement was noticeable only when the patient swallowed; moderate enlargement, when an obvious goitre was present; and large. In most cases there was some increase in the size of the thyroid after treatment began, but usually this was only slight and regression occurred after six months to a year.

At present two patients have large goitres which cause no inconvenience. No thyroidectomy has been advised, as in both cases some decrease in size is expected. Two other patients had large goitres, but one of these has been removed surgically and the other has regressed to slight to moderate size, thiouracil administration having ceased. One patient with a moderate enlargement underwent thyroidectomy, and five patients at one time showed moderate enlargement, but in all these cases the thyroid is now small. Four patients have thyroids of slight to moderate size, and in eight the thyroid has shrunk from this size to only slight enlargement. In the remaining 40 cases the enlargement is slight.

Complications due to Thiouracil

In five cases skin rashes have occurred in the early weeks of thiouracil therapy. Unfortunately, as all the patients were at the time taking phenobarbitone it is impossible to be sure whether this drug or the thiouracil was responsible. In all cases the rashes faded in a few days after withholding phenobarbitone.

An unexplained fever occurred in four cases, but the temperature settled to normal in a few days without any alteration in treatment.

Granulopenia (less than 1,000 neutrophil polymorphs per cmm of blood) has been noted in eight cases. One patient reported because she had developed a sore throat. She had originally presented with thyrotoxicosis in July, 1944, and had been treated with thiouracil for 16 months, thiouracil then being stopped. She had remained in good health without thiouracil for 18 months when a mild relapse occurred. Thiouracil, 0.2 g daily, was given once more. On the sixth day after beginning thiouracil her granulocyte count was 2,100 per cmm. Three days later a sore throat developed, and the next day she was found to have 185 granulocytes per cmm of blood. Thiouracil therapy was stopped and penicillin was given. The cell count rose rapidly and on the third day after stopping thiouracil showed 2,600 granulocytes.

In the remaining seven cases of granulopenia there were no symptoms or signs of any infective process, the granulopenia being revealed by routine blood examination. The duration of treatment before the onset of granulopenia in these cases varied from four weeks to 16 months. In three cases the polymorph count was 384, 400, and 440 cells per cmm, but the patients felt in their usual state of health. In all seven cases the cell count rose rapidly when thiouracil was stopped, and none developed an infection or was given any antibiotic treatment.

The further management of patients who have had granulopenia has varied. As already mentioned, the one who developed an infection refused operation and is moderately toxic, and one with granulopenia and no infection has had a thyroidectomy. Four patients have resumed treatment with thiouracil or methyl thiouracil, and over periods varying from six to 18 months have shown no further granulopenia. One patient proved sensitive to both thiouracil and methyl thiouracil, but after a slight relapse off thiouracil his condition is satisfactory. In the last case the granulopenia occurred on the day that thiouracil was stopped for a period of observation, and so far no thyrotoxic symptoms have recurred. In cases given thiouracil after having had a granulopenia the white cell count has been observed three times weekly for the first month and thereafter every six weeks.

Other Complications

Myxoedema occurred in a woman aged 66 who was admitted with severe thyrotoxicosis complicated by an acute mania. She responded rapidly to thiouracil, and medication was stopped after seven months. Nineteen months after cessation of the thiouracil she was found to be severely myxoedematous, with a basal metabolic rate 71% of normal. The myxoedema in this case is not likely to be the result of thiouracil administration.

Diplopia occurred in two cases. In one it lasted for only a few weeks during the early months of treatment. In the other it was a troublesome symptom that persisted for about six months. The cause was probably exophthalmic ophthalmoplegia.

Pregnancy

There have been three pregnancies in women taking thiouracil. In the first case the mother was kept on thiouracil throughout pregnancy. The infant was born alive with an easily palpable, rather hard thyroid. This became impalpable after feeding for one month on pooled human milk, and the infant is now a normal child of 2½ years. In the second pregnancy thiouracil was not given for two months before delivery; Lugol's iodine, 10 minims (0.6 ml.) daily, was given instead. A normal infant was born. In the third pregnancy thiouracil was stopped four months before delivery and iodine was not given. A normal infant was born in this case also. Both pregnancies in which the thiouracil was stopped before delivery were followed by relapse of the thyrotoxicosis within three months of delivery.

Auricular Fibrillation

Ten cases of thyrotoxicosis complicated by auricular fibrillation have been treated. In four the fibrillation was continuous and was associated with congestive heart failure, but in all cases the history suggested that failure had been present for only a few weeks. In the first case regular rhythm was established after 15 days' treatment with thiouracil alone. In the second, auricular fibrillation persisted after nine weeks' treatment with thiouracil alone, although the thyrotoxicosis appeared to have been controlled. When regular rhythm was restored by quinidine after digitalization a transient motor aphasia occurred, presumably the result of a cerebral embolism. The third and fourth cases were treated successfully by quinidine on admission to restore regular rhythm, and then by thiouracil to control the thyrotoxicosis. In five patients paroxysmal fibrillation was shown by electrocardiography to be present. In four of these the fibrillation was controlled by thiouracil alone, but in the fifth the paroxysms of fibrillation were so frequent and the patient's condition so distressed by cardiac failure that digitalis was given, and regular rhythm

was restored by quinidine before thiouracil was used. In the tenth case fibrillation was known to have been present for three years and heart failure for two months. The patient had been receiving digitalis since the onset of the fibrillation. She was treated by complete rest in bed and injections of mersalyl, and methyl thiouracil, 0.2 g. daily, with steady improvement. After three weeks the digitalis was stopped and the improvement continued. The oedema had gone after six weeks.

In all ten cases, once the thyrotoxicosis was adequately controlled, the administration of digitalis and quinidine, if they had been given, was stopped, and treatment was continued with thiouracil alone. In the last case slow fibrillation continues without evidence of heart failure, but in the others no recurrence of fibrillation has been observed while on thiouracil. The periods of observation since restoration of regular rhythm vary from seven to 27 months.

Koilonychia

Koilonychia has been noted in seven of the 51 cases seen between October, 1945, and January, 1948 (Table III). All

TABLE III.—Showing the Haemoglobin Level in the Patients having Koilonychia

Case	Haemoglobin on Admission	Haemoglobin After 1 Year
1	86%	86%
2	85%	86%
3	68%	68%
4	78%	94%
5	94%	—
6	45%	—
7	86%	—

were in women, and a history of thyrotoxicosis lasting a year or more before reporting for treatment was usual. Only Case 6 was given iron. The haemoglobin level (Haldane) on admission is shown in the table. In four of the cases in which one year's follow-up has been possible the koilonychia has entirely disappeared and a normal strong nail has grown. None of these cases was given iron, and in three there was no rise in the haemoglobin level.

Discussion

In this series of cases thiouracil has proved satisfactory in the treatment of thyrotoxicosis, and only one patient of those given thiouracil alone has had to obtain lighter employment because of the disease. The disability in this case was probably less than that of the first patient who had a thyroidectomy and in whom symptoms returned after the operation despite a basal metabolic rate 95% of normal. The symptoms in this latter case are similar to those described by Martin (1948), and it is curious that they were not present when the basal metabolic rate was reduced to 100% by thiouracil.

The one serious complication encountered has been granulopenia, and only a high degree of co-operation on the part of the patients has avoided a catastrophe. Several have reported to the hospital or to their own doctors with sore throats, but only one was found to have a granulopenia. The position of those in whom a granulopenia was discovered by routine blood examination is not certain. Agranulocytosis usually occurs with great rapidity, as in the case in the present series, and in the only patient with granulopenia whom it was possible to keep in hospital for observation the neutrophil polymorph count remained low for 18 days while thiouracil was given, rose when thiouracil was withheld, and remained normal when methyl thiouracil was used. This suggests that granulopenia is not necessarily a prelude to agranulocytosis. Five patients who developed granulopenia were again given thiouracil or methyl thiouracil after an interval off the drug had allowed

recovery. Only one of these developed a further granulopenia, which appeared in the first few days after starting the drug.

The management in pregnancy is a matter requiring further observation. The enlargement of the infant thyroid that was found when thiouracil was given throughout pregnancy has been previously reported by Eaton (1945). It is probably best to stop thiouracil administration some months before delivery. As thiouracil is excreted in maternal milk no mother taking thiouracil should suckle her child (Williams *et al.*, 1944; Chesley, 1944).

Although thiouracil alone may restore regular rhythm in thyrotoxic auricular fibrillation it does not always do so, and sometimes, when the thyrotoxicosis is slow in responding, may take a long time, during which there is some danger of embolism. After the episode of embolism which occurred in the second case with auricular fibrillation it was thought safest to establish regular rhythm with quinidine at the earliest possible moment in all cases where the fibrillation was not of long duration. Accordingly such cases were admitted as emergencies to the ward, digitalized on admission, and then given quinidine. In many cases, however, like the one here reported, the fibrillation may be allowed to continue and the heart failure will respond to thiouracil alone (Cookson and Staines, 1947).

Koilonychia has been noted previously in thyrotoxicosis and its disappearance after treatment with thiouracil reported by Cooke and Luty (1944). It is evident from their records, and from the observations on the first three cases shown in Table III, that the koilonychia in thyrotoxicosis is unrelated to the haemoglobin level.

Summary

A series of 62 consecutive cases of thyrotoxicosis were treated with thiouracil or methyl thiouracil. All cases responded to the drug, and only one man treated with thiouracil alone had to obtain lighter employment. The time spent off work was usually less than six weeks from starting thiouracil therapy. In three cases the results were regarded as unsatisfactory.

Thyroidectomy was performed in two cases, the indications being persistent granulopenia and excessive thyroid enlargement respectively. One patient died from suppurative bronchiectasis.

Granulopenia occurred in eight cases. In one there was infection, which was controlled by penicillin; the others were found on routine blood examination. Four of these cases have resumed thiouracil therapy without further granulopenia.

One patient developed myxoedema after being off thiouracil for 19 months.

Two patients developed transient diplopia, probably due to exophthalmic ophthalmoplegia.

Three pregnancies occurred. Thyroid enlargement was noted in the child in the only case in which thiouracil was given throughout pregnancy.

The treatment adopted for continuous auricular fibrillation of short duration was to restore regular rhythm with quinidine as soon as possible, and to stop quinidine administration when the thyrotoxicosis was controlled. Paroxysmal fibrillation responded to thiouracil alone.

Koilonychia was noted in seven of 51 cases. In three of these normal nails were formed in about one year without any rise in haemoglobin.

I wish to thank Professor R. S. Aitken for giving me charge of these patients during my term as his assistant.

THYROTOXIC AURICULAR FIBRILLATION TREATED WITH THIOURACIL

BY

J. F. GOODWIN, M.D., M.R.C.P.

(Research Fellow and Tutor in Therapeutics, University of Sheffield; First Assistant, Royal Infirmary, Sheffield)

Thiouracil compounds have been shown to be effective in causing reversion to sinus rhythm in cases of thyrotoxic auricular fibrillation. Cookson (1945) secured reversion in three out of 10 cases treated with thiouracil alone, but noted that one of his failures had mitral stenosis. Out of Nussey's (1944) three patients sinus rhythm was restored by thiouracil in one. In a later paper Cookson and Staines (1947) claimed reversion to sinus rhythm with thiouracil alone in eight out of 16 patients after an average of 35 days' treatment, the longest period being 15 weeks and the shortest four days. Associated cardiac disabilities (mitral stenosis) are reported in only one of the patients with persistent fibrillation, McGavack and others (1945) reported reversion to sinus rhythm with thiouracil alone in 12 out of 18 patients, one of the 12 having bundle-branch block. Grainger's (1945) two patients with fibrillation both reverted spontaneously to sinus rhythm. Clarke (1948) achieved reversion to sinus rhythm in three out of six patients with thiouracil alone, while Wilson (1946) reported reversion to sinus rhythm in five out of six cases included in the present series.

The object of this communication is to present briefly the effect of treatment with thiouracil drugs on cases of auricular fibrillation due to thyrotoxicosis, and to determine the value of certain associated factors in assessing the likelihood of reversion to sinus rhythm without additional therapy. Out of 144 thyrotoxic patients attending the endocrine clinic 28 (19%) had auricular fibrillation. All had been treated with thiouracil compounds (thiouracil, methyl thiouracil, or propyl thiouracil) for not longer than two years, and were cases of secondary thyrotoxicosis. Their ages ranged from 32 to 68 years (average, 50). Thirteen patients reverted to sinus rhythm with thiouracil treatment: quinidine was deliberately omitted in order to investigate the long-term effects of thiouracil on auricular fibrillation. The average amount of thiouracil compound given was 50 mg. daily. Six of the patients received digitalis to control ventricular rate and congestive failure.

Apart from 11 patients who had a systolic blood pressure of 160 mm. Hg or greater, there was no clinical evidence of cardiovascular disease. Cardiomegaly was present in 18 cases. In no case was the systolic blood pressure greater than 190 mm. Hg. Two patients with persistent auricular fibrillation have been excluded from the analysis, as the thyrotoxicosis is not yet under control.

Group I: Patients in whom Auricular Fibrillation Persisted

In each of the 13 patients in this group the thyrotoxicosis was well controlled but the fibrillation persisted. The average age was 52 years, and the duration of symptoms before treatment varied from three months to 12 years, the average being 77 months. The duration of treatment up to the present has varied from one month to two years, the average being 11 months. Before treatment was started five patients had a systolic blood pressure of 160 mm. Hg or greater, while slight to moderate cardiomegaly was present in nine patients. The cases are summarized in Table I.

TABLE I.—Group I Cases

Case No.	Age	Duration of Disease Before Treatment	Duration of Treatment	B.P. Before Treatment	Heart Enlarged Before Treatment	Digitalis Given	E.C.G. Before Treatment
1	55	9 years	8 months	170/75	+	—	AF only
2	57	4 "	2 years	120/60	—	—	RBBB
3	68	3 "	6 months	170/72	+	D	AF only
4	52	3 months	8 "	140/70	+	—	CCI
5	60	Not known exactly	1 month	170/110	+	D	—
6	52	18 months	—	—	—	D	—
7	61	12 years	6 "	130/100	—	D	—
8	49	12 "	9 "	140/75	+	—	—
9	45	12 "	1 year	150/85	—	—	AF only
10	35	Not known exactly	18 months	130/70	+	D	CCI
11	53	3 months	8 "	170/110	—	—	AF only
12	57	9 years	9 "	170/70	+	—	CCI
13	38	3 "	1 year	150/85	+	—	AF only

D = Digitalis. CCI = Chronic coronary insufficiency. RBBB = Right bundle-branch block. AF = Auricular fibrillation.

Electrocardiographic Changes.—Electrocardiograms were recorded from nine patients before treatment. Apart from auricular fibrillation, four were abnormal: right bundle-branch block was found in one subject, while three others showed chronic coronary insufficiency. Of the four patients showing abnormal curves, only one had hypertension, and of the five patients with hypertension only one had electrocardiographic abnormalities other than auricular fibrillation.

Fig. 1 is an electrocardiogram of Case 12, representative of the more severe type of changes seen; Fig. 2 (Case 4) is representative of minor changes; and Fig. 3 is an electrocardiogram of Case 2, showing right bundle-branch block.

Group II: Patients in whom Auricular Fibrillation Reverted to Sinus Rhythm

The average age of the 13 patients in this group was 49 years. The duration of the disease (but not necessarily of the fibrillation) before treatment varied from four months to 10 years, the average being 50 months, while the duration of treatment before sinus rhythm was restored varied from one week to four months, the average being six weeks. Only one patient received digitalis. Six patients had a systolic blood pressure of 160 mm. Hg or greater before treatment. Case records are summarized in Table II.

FIG. 1.—Case 12.—There is right axis deviation. Auricular fibrillation. The Q wave is present in Lead III (amplitude 2–2.5 mm.; duration less than 0.04 sec.). The S wave in Lead III is only slightly greater in amplitude than the Q wave (3–4 mm.). There is sharp inversion of the T waves in Leads II, III, and CF₄. (1 cm. = 1 mv.) The ST segment is depressed by 0.25 mm. in Lead I, 0.5–1 mm. in Lead II, and 1.5 mm. in Lead CF₄. (No digitalis.)

FIG. 2.—Case 4.—Auricular fibrillation. There is a small Q wave (1 mm. amplitude) in Lead II. There is 0.5 mm. elevation of the ST segment in Leads II and III and 1 mm. elevation in Lead CF₄. (1 cm. = 1 mv.) The I wave is inverted in Lead CF₄. One premature ventricular contraction in Lead II. (No digitalis.)

TABLE II.—Group II Cases

Case No.	Age	Duration of Disease Before Treatment	Duration of Treatment Before Reversion	B.P. Before Treatment	Heart Enlarged Before Treatment	Digitalis Given	E.C.G. Before Treatment
14	48	6 years	1 week	135/65	+	—	AF only
15	56	4 months	2 months	166/88	+	—	—
16	45	4 years	2 "	180/70	+	—	CCI
17	50	10 "	2 "	165/80	+	—	AF only
18	54	4 "	2 weeks	126/80	+	—	"
19	41	2 "	1 month	155/95	+	—	"
20	—	The only information available regarding this patient indicates that reversion occurred after thiouracil treatment					
21	32	3½ years	4 months	145/95	—	—	AF only
22	56	Not known exactly	2 "	186/100	+	—	"
23	60	6 months	6 weeks	160/110	+	D	"
24	59	9 years	1 month	140/80	—	—	"
25	39	5 "	1 week	150/95	—	—	"
26	45	6 months	3 weeks	190/90	+	—	AF only. (After reversion to SR 1st degree A° block seen.)

D = Digitalis. SR = Sinus rhythm. CCI = Chronic coronary insufficiency. AF = Auricular fibrillation.

Electrocardiographic Changes.—Electrocardiograms were obtained in 11 patients before treatment. In two subjects (both with slight hypertension) changes indicating chronic coronary insufficiency in addition to auricular fibrillation were present, while in a third patient first-degree A° block was seen after sinus rhythm had been restored.

It may be said, therefore, that six patients showed some evidence suggesting cardiovascular disease associated with but not due to thyrotoxicosis.

Discussion

These results indicate that reversion to sinus rhythm may be expected from thiouracil treatment alone in approximately 50% of cases, and show that thiouracil compound are at least as effective as surgery in this respect (Hurxthal 1930; Anderson, 1932). Reversion is not, as Cookson (1945) suggests, a satisfactory measure of the control of the disease, although no patient has been shown to revert to sinus rhythm unless the disease is fully controlled. Of the 28 cases, 26 were rendered clinically non-toxic by

thiouracil drugs, so that persistence of auricular fibrillation suggests that some other cardiac abnormality might be an important factor in the cases in the second group. Six patients in this group showed clinical or electrocardiographic stigmata suggesting associated cardiovascular disease, compared with seven patients in the first group. Systolic blood pressures of 160 mm. Hg or over occurred in five patients in Group I and six patients in Group II; but electrocardiographic abnormalities were present in four out of nine patients in Group I and two out of 11 patients in Group II.

The average period of treatment to obtain reversion in this series was six weeks, while the average duration of symptoms before treatment was greater in Group I than in Group II. It is unfortunate that the duration of fibrillation before treatment could not be ascertained. Digitalis was given to a larger number of patients in Group I than in Group II. No difference in the ability to abolish fibrillation was detected in any one of the three thiouracil compounds used. Finally, there was a higher incidence of electrocardiographic abnormalities in the patients with persistent fibrillation.

Conclusion

In view of these findings it seems reasonable to conclude that if sinus rhythm is not restored by thiouracil alone after a maximum period of four months auricular fibrillation may become permanent unless other measures are taken. In these circumstances it is suggested that quinidine should be given to restore sinus rhythm if the thyrotoxicosis is under control. If thyrotoxicosis has not been effectively controlled by thiouracil, alternative treatment should be considered. There appears to be no reliable method of gauging the prospect of stopping fibrillation with thiouracil alone in any given patient, but the presence of electrocardiographic abnormalities indicating associated cardiovascular disease lessens the chance of reversion. Sinus

rhythm is also less likely to return if the patient has a history of symptoms for more than 4½ years before treatment. It is possible that digitalis tends to establish the arrhythmia, and its use should be avoided except where there is associated congestive heart failure.

I wish to thank Professor E. J. Wayne for helpful criticism, and Dr. Andrew Wilson for his notes on the earlier cases in the series.

PHENOLOGY OF BRITISH HAY-FEVER PLANTS AND ITS SIGNIFICANCE TO ALLERGISTS

BY

H. A. HYDE, M.A., F.L.S.

(From the National Museum of Wales, Cardiff)

It is generally accepted that pollen can cause hay-fever only if it is actually present in the air and in significant quantity: in other words, that hay-fever is exclusively an inhalant allergy. Skin tests, it seems to be agreed, are very helpful in diagnosis but are by no means infallible. Even if a patient gives a positive reaction to a reliable pollen extract it is necessary before making the diagnosis to show that his symptoms coincide in time with the incidence of pollen of the type concerned; if they do not he should be presumed non-allergic to that type of pollen. It is therefore important that those interested in hay-fever and pollen asthma should know what pollens are likely to be present in the air at various times and in what relative quantities.

The study and recording of periodical phenomena of this kind is known as phenology.¹ During the past seven years the phenology of British hay-fever plants, and in particular of atmospheric pollen, has been studied closely by the method of pollen-trapping. The pollen caught on glass microslides, exposed day by day for a year or more at some fourteen stations in Great Britain—from South Wales and London to as far north as Aberdeen—has been analysed at Cardiff. Some of the results so far obtained² are summarized in the accompanying diagram.

The principal pollen types can be grouped under three headings—trees and shrubs, grasses, and other herbs. All the most important tree pollens are liberated in the spring. Grass pollens dominate in the months of June and July. Thereafter relatively little pollen is present in the air except locally.

The thick lines in the diagram indicate the periods during which the respective pollens are likely to be present in the air in lowland localities in the south of Great Britain. The thinner extensions of the thick lines indicate that the pollens are usually present in smaller quantities both before

FIG. 3.—Case 2.—There is right axis deviation. Auricular fibrillation. The QRS duration is 0.12 sec. in Leads III and CF, and 0.1 sec. in Leads I and II. The T wave is biphasic in Lead III and is sharply inverted in Lead CF. There is a secondary R wave in Leads II, III, and CF. One premature ventricular contraction can be seen in Lead III. These changes are indicative of intraventricular block, probably right bundle-branch block (No diet alis) (1 cm. = 1 mv.) (It is of interest that further studies two years later, using augmented unipolar leads, showed complete right bundle-branch block.)

¹Or phenomenology. Greek *phænomēnon*, an appearance; *logos*, a discourse.

²Hyde, H. A., and Williams, D. A. "Studies in Atmospheric Pollen," I-III. *New Phytologist*, 43-5, 1944-6. Hyde, H. A. "Studies in Atmospheric Pollen," IV-V. Unpublished.

filter through good-quality filter paper. The filtrate should be clear. Add 0.5 ml. of the filtrate to 5 ml. of Benedict's qualitative reagent and treat as before.

With a Duboscq colorimeter set the unknown at 10 and read the standard. Let the reading be R.

$$\frac{(40 - R) \times 5 \text{ (dilution)}}{2 \text{ (for using 0.5 instead of 0.25)}} = \frac{(40 - R) \times 5}{2} \text{ grammes per litre}$$

That is, we can read the amount direct as if we are using 0.1 ml. of urine (from the table and Fig. 1).

With the Lumetron 2 ml. of the supernatant fluid is mixed with 8 ml. of water (as usual). The transmission is read on the line of 0.1 ml. of urine. For the amount of sugar in milk divide by 10 to get grammes %. The result is multiplied finally by 67/50, the reduction factor for lactose.

Medical Memoranda

Surgical Treatment of Rabies

Cauterization of bites by rabid animals, as recommended by the Pasteur Institutes, might advantageously be combined with the modern surgical technique of excision of contaminated wounds. Complete destruction of the virus by cauterization alone is at best fortuitous, and unlikely in extensive, deep, and punctured wounds.

I have recently seen three fatal cases of rabies following dog-bites. One patient received no prophylactic treatment, but the other two (Anglo-Indian children aged 2 years 3 months and 2 years 5 months) had their wounds thoroughly cauterized shortly after infliction. They were also given a full course of anti-rabic vaccine (5 ml. subcutaneously every day for 14 days), although there was an unavoidable delay of two days in instituting vaccine treatment in one case, and of nine days in the other. The risk of rabies in these two patients was admittedly serious, as the bites were facial and of considerable severity.

I suggest the following procedure in the treatment of wounds inflicted by rabid or presumably rabid animals:

- (1) Thorough cauterization of the wound with concentrated nitric or pure carbolic acid. This is done immediately, and on no account delayed until preparations for operation have been completed.
- (2) The skin is carefully sterilized over a wide area with pure rectified spirit, and then with tincture of iodine.
- (3) The aim of surgical treatment is complete excision *en bloc* of all lacerated and potentially infected tissue. All dissection takes place in uncontaminated tissue-planes, with an ample margin of clean tissue to act as a barrier, a fresh knife being used for each wound. Scrupulous care is required to keep contaminated instruments separate (e.g., those used to put tension on the edges of the original wound), and at the earliest moment all contaminated instruments are treated with pure lysol, washed, and re-sterilized.
- (4) The surgical wound resulting from excision is then cauterized with the same agent that was used originally. After haemostasis has been secured the wound is left unsutured and dressed.

This technique is open to certain objections. Dr. N. Veeraraghavan, director of the Pasteur Institute, Coonoor (personal communication), observes in experimental animals that rabies is produced as quickly by inoculation of the sciatic nerve as of the subdural space. He raises the question of similar inoculation of nerve trunks during surgical excision of the wound, although it seems likely that this danger could be avoided by immediate cauterization of the surgical wound and careful technique to avoid contamination in the operative field by the surgeon and his instruments.

There seems ground for experimental work to establish the value or otherwise of the above procedure. If proved to be effective, the method would be indicated in cases with strong

presumptive evidence of infection with rabies; in cases where the wounds were amenable to radical excision; and in centres possessing adequate surgical facilities. In more remote areas the present method of treating wounds by cauterization alone would continue to be employed. In either case, a full course of anti-rabic vaccine would be necessary.

Hypnosis and Suggestion in Obstetrics

Below are given the histories of three cases in which use was made of the power of suggestion to the subconscious mind so that the activity of the normal conscious levels and the concomitant highly developed critical faculties were temporarily suspended.

CASE REPORTS

Case 1.—The patient, a primigravida aged 21, was admitted to hospital as an emergency with a diagnosis of obstructed labour, having been in the second stage of labour for six hours after a first stage of about twenty-four hours. On examination rather painful uterine contractions were still present, although they were much less severe than they had been, the vertex was engaged but a large caput had formed, and there was excessive moulding of the foetal head. The cause of the delay appeared to be a relative disproportion between the presenting part and the outlet, together with incomplete anterior rotation of the occiput. The head was fitting extremely tightly in the birth canal and seemed completely "stuck." A condition of light hypnosis was induced and the patient was instructed to relax, which she did sufficiently well to enable the occiput to be rotated more to the front and the forceps to be applied correctly. During delivery of the baby the mother was able to co-operate and use her own expulsive muscles while traction was being made. She later stated that she had had no actual pain but that she felt "like another person." Although the tissues of the perineum were very thick, only a very small episiotomy was required. The placenta was expelled naturally after 20 minutes, and the baby, which cried lustily, weighed just over 10 lb. (4.5 kg.).

Case 2.—A primigravida aged 32 with a twin pregnancy was admitted to hospital as a booked case, having regularly attended the antenatal clinic. Her membranes ruptured two hours after labour pains had started, and progress was very slow, as is often the case with multiple pregnancies, so that towards the end of the third day of labour she was much distressed and exhausted in spite of the administration at intervals of pethidine hydrochloride in doses of 100 mg. each and other sedatives such as chloral hydrate and potassium bromide. The cervix was then a little more than two-thirds dilated but was very oedematous, and the patient constantly reiterated her strong desire to bear down with each contraction. Doubtless this inability to relax properly during the first stage was partly responsible for the oedema and slow dilatation of the cervix. In spite of the presence of painful uterine contractions therapeutic suggestion was attempted, and after about fifteen minutes the patient began to respond and became much quieter and more relaxed. A few minutes later she was sleeping, although strong contractions were still occurring. The suggestion of "No pain" was continued at intervals for another ten minutes or so, and she remained asleep for some hours. When re-examined later, on awakening, her condition was much improved, the cervix being nearly fully dilated and the oedema having disappeared. She then stated that she felt much refreshed and that all she could remember was a feeling of drowsiness associated with a sensation of being "far away—as if I were floating in space." The rest of the labour progressed normally and satisfactorily and both babies were born in good condition.

Case 3.—A primigravida aged 24 was admitted to hospital owing to a prolonged first stage and an impending uterine inertia. She had been in labour for between two and three days and was becoming exhausted and depressed. On examination the cervix was nearly three-quarters dilated and the membranes were still intact. A light hypnotic sleep was then induced and the suggestion made that she would sleep until it was time to "push the baby out." She slept, although slightly restless now and then, for some hours, and soon after waking second-stage contractions began and labour then continued normally and uneventfully.

These three cases illustrate to some extent what can be achieved if the so-called "subconscious mind" can be utilized in aiding the removal of fear and tension and the promotion of relaxation both of mind and of body.

Reviews

CLINICAL ENDOCRINOLOGY

Clinical Endocrinology. By Laurence M.D. (Car), and others and Students. By M.C.P., and Martin Hynes, M.D. (Car), by Sir Lionel Whitby, C.V.O., M.C., M.D., F.R.C.P., D.P.H. (Pp. 222; 8 plates and 22 text-figures. 15s.) London: J. and A. Churchill. 1948.

There have been many books on endocrinology in recent years, and a fresh one therefore needs to be considered critically. But this work fully justifies itself, and will be of great value to those who need an unbiased survey of the subject in compact form and at a very reasonable price.

This book is a model of conciseness without irrelevance. Within its 220 pages will be found a clear presentation of the present state of orthodox clinical experience in endocrinology. The authors rightly confine themselves to recognized sound knowledge, and speculation and hypothesis are reduced to a minimum. The book is divided into the traditional sections, and at the end of each is a well-chosen list of modern references, the value of which is increased by the inclusion of the full titles of all papers quoted. Perhaps the severest test of a work of this type lies in its handling of the complex disturbances referable to dysfunction of the sex glands. Nearly half the book is devoted directly or indirectly to such disturbances, and a clear account is given of this difficult subject. The uses, and equally the shortcomings, of the sex hormones in therapy are critically presented, and undue enthusiasms are avoided. The relations between Cushing's syndrome and the adrenogenital syndrome are well described. Pseudohermaphroditism is included in the latter section, and the relationship of this to adrenal hyperfunction is lucidly explained. In discussing the relative places of surgery and of thiouracil in the treatment of thyrotoxicosis, the author rightly stresses the importance of considering the social and domestic circumstances and the quality of available surgery.

There are few omissions of importance. The value of urinary calcium excretion in the diagnosis of hyperparathyroidism is not adequately stressed, and references to the recent work of Albright on this disease are not given. But elsewhere the treatment is up to date and well balanced. There is an excellent index, which adds to the value of a book which can be thoroughly recommended to all who need a straightforward guide to modern clinical endocrinology.

CUTHBERT COPE.

PRACTICE OF ENDOCRINOLOGY

The Practice of Endocrinology. Edited by Raymond Greene, M.A., D.M., M.R.C.P. The Practitioner Textbooks. (Pp. 366; 52 illustrations. £2 12s. 6d.) London: Eyre and Spottiswoode (Publishers), Ltd. 1948.

This is one of the *Practitioner* series. It is edited by Raymond Greene, with the collaboration of A. C. Crooke, Donald Hunter, R. D. Lawrence, J. M. Robson, F. F. Rundle, and P. H. Sandifer. As often the case in a work written by several people, authors of the different sections vary greatly in the way they handle their subjects.

Raymond Greene's contributions are scholarly and practical, and pleasantly seasoned with wit. His chapters on the thyroid gland and on adiposity are outstandingly good. The description of thyrotoxicosis is full, and enlivened by short but vivid descriptions of cases; and his account of treatment not only gives a very fair assessment of the relative merits of thiouracil and thyroidectomy but also affords due attention to preventive and psychological factors, including the patient's private worries and the dangers of disciplinary ward sisters. Little is said about the management of the ophthalmic form of Graves's disease (which can be a major clinical problem), and Ida Mann's views on treatment with thyroid or testosterone are not discussed.

The sections on the pituitary and the adrenal by A. C. Crooke are in an entirely different style. For one thing, they contain more references than are provided by all the other chapters put together. As the book is for general practitioners, to provide them with so much detail and so many references seems

rather like giving the complete sixteen-volume *Oxford Dictionary* to a foreign tourist. For example (radiological changes in the chiasmal syndrome, p. 31): "Kornblum and Osmond said that the anterior clinoid processes were elongated and eroded in 37.9% of their cases, and in 23% they were elongated, but otherwise normal. In 18.9% they were affected differently on the two sides. . . . [They] found erosion of the tuberculum in 58.2% of their cases." This standard of detail is kept up for pages on end, smothering the essentials in minutiae.

Among the other contributors, Lawrence writes on diabetes with his usual simplicity and brevity, and in one of the shortest articles of the book manages to include all the major facts and practical points the practitioner could wish for. Donald Hunter and P. H. Sandifer give equally succinct accounts of the parathyroids and the thymus respectively. There are more than fifty excellent plates in the book, and the coloured printing is beautifully done. The book sets a high standard and is a welcome addition to the literature of endocrinology.

RICHARD ASHER.

INTRODUCTION TO ENDOCRINOLOGY

General Endocrinology. By C. Donnell Turner, Ph.D. (Pp. 604; illustrated. £1 15s.) Philadelphia and London: W. B. Saunders Company. 1948.

The author is Associate Professor of Zoology at North Western University, and this determines the keynote of a biological approach. The book "is intended primarily for advanced investigators and practising physicians." The introduction contains a historical review, and the second chapter, on biology, ranges over many zoological species. The chapter on the thyroid is sound and comprehensive, though brief, and includes a consideration of the mechanism of thyrotropic hormone, radioactive iodine, and thiouracil. The renal theory of action of parathormone is well presented. The account of the physiology and biochemistry of the adrenal medulla is particularly good. The adrenocorticotrophic factor of the pituitary is not adequately dealt with, when account is taken of the experimental and clinical work of the past two years; the "alarm reaction" is given but a small paragraph. The section on the physiology of the ovary is one of the best contributions to this subject.

On the whole the book is an excellent and sound introduction to endocrinology, providing as it does all the advantages of a comparative morphological approach. Some 160 illustrations and diagrams augment its value and clarity.

S. LEONARD SIMPSON.

PSYCHOBIOLOGY

The Psychology of Behaviour Disorders. A Biosocial Interpretation. By Norman Cameron, M.D., Ph.D. (Pp. 622. 25s.) New York: Houghton Mifflin Company. London: H. K. Lewis and Co.

The psychobiological school of psychiatry, initiated by Adolf Meyer, attempted to interpret the behaviour of psychiatric patients as that of unitary individuals. No symptom could be referred to as solely the effect of, say, a lesion in the brain or the manifestation of an abnormal hereditary tendency; every phenomenon was the product of an interaction between an individual, a psychobiological unity, and the total environment. This teaching provided a valuable corrective tendency, but it has not proved very productive in research. Dr. Cameron's work stems from this school, but takes a more extreme position. Every phenomenon in human behaviour is related to the psychological aspects of social relations. This means a complete break with psycho-analysis, no less than with neurological psychiatry, genetics, constitutional medicine, and physiological pathology. There are no instincts, no conditioned reflexes. In an infant the act of sucking has no reflex basis, it is a manifestation of his attitude to his mother. The special abilities of the surgeon are solely the result of learning and have no basis in innate dexterity. There is no brain pathology for schizophrenia; it can be derived from normal behaviour on the basis of adaptive insufficiency and habit deterioration. Personality is the organization of interlocking behaviour systems that each of us develops through learning processes.

The author sees the world in shades of light and dark and without colour, though his analysis of the factors of strain, the processes of habituation, which arise from human relations

and play their part in psychiatric illness, is often acute and instructive. It is not in fact germane to his case to pretend that this is the whole of the picture, and his thesis would have been much stronger if he had left room for specific effects from specific agents. As it is, he is unable to explain how in indistinguishably different environments one patient becomes an obsessional, another schizophrenic.

ELIOT SLATER.

GYNAECOLOGICAL HISTOLOGY

Gynaecological Histology. By Josephine Barnes, M.A., D.M., M.R.C.P., F.R.C.S., F.R.C.O.G. (Pp. 242; 162 illustrations. £1 10s.) London: Harvey and Blythe.

This small volume contains 162 photomicrographs which are intended to illustrate the histology of gynaecology. The selection has been made with care and is fairly representative. In addition to short descriptions below each illustration Miss Barnes has given a brief résumé of the normal histology of the female pelvic organs, with a brief classification of gynaecological affections.

The best feature of the book is the quality of the majority of the photomicrographs, and students should have little difficulty in learning the peculiarities of the different types of histological material if the illustrations are studied carefully. Figures 22, 23, 24, 26, and 63, however, are flat and below standard.

The book is much too short, and is uninspiring. The classification and description of tumours of the ovary is far too elementary and unsound in many ways. The description of affections of the vulva is not up to date. The book reflects none of the erudition of a Robert Meyer, of an Oscar Frankl, or of an Emil Novak, and the price is perhaps too high for a work of this kind.

WILFRED SHAW.

HISTOLOGY FOR MEDICAL STUDENTS

Human Histology. A Guide for Medical Students. By E. R. A. Cooper, M.D. Second edition. With foreword by F. Wood Jones, F.R.S., F.R.C.S. (Pp. 432; 4 coloured plates and 257 in text. £1 7s. 6d.) London: H. K. Lewis and Co. 1948.

This book claims to be a guide; its subject is human histology; and it is written for medical students. Practically all the illustrations are from human material, and for the most part are photomicrographs at low magnification of the kind of preparation given to students in the average histology class. The style of the book is simple and direct. The text is enlivened by short appropriate physiological explanations, and some basic general pathology is included. Each chapter is followed by a short, concisely written practical section. In this, the second edition, the chapter on the blood, marrow, and haemopoiesis has been rewritten. The general character of the book is unaltered. It remains a reliable and companionable bench book of adequate size and compass for the medical student taking an ordinary pass examination.

GEOFFREY HADFIELD.

Dr. Windsor C. Cutting in his *Manual of Clinical Therapeutics* (second edition; pp. 712; illustrated; £1 5s. Philadelphia and London: W. B. Saunders Company, 1948) has tackled with some success the difficult task of presenting encyclopaedic information in a form small enough for the pocket. Without attempting to go into great detail he presents a rational system of therapy, and the book is refreshingly free from the recipes for complicated cough mixtures that are apt to form so prominent a part of similar manuals. The diseases are classified according to aetiology or the system involved; each disease is clearly and concisely described, some of the articles being masterpieces of condensation. Only minor criticisms can be made of the treatment and management recommended. A white cell count twice weekly during thiouracil therapy is now generally regarded as an excess of caution, and it is interesting to read that expense may be a limiting factor in testing the urine and blood during chrysotherapy. The use of D.D.T. in louse infestation is curiously omitted, though it is listed in the appendix of recommended drugs. There are useful sections on poisons and clinical procedures, but the value of those on diet and drugs is limited for the English reader, as the former refers to the American dietary and the latter to the U.S. Pharmacopoeia. Without attempting too much, the author has written a useful and readable guide to modern therapeutics.

BOOKS RECEIVED

(Review is not precluded by notice here of books recently received)

Current Therapy 1949. Edited by H. F. Conn, M.D. (Pp. 672 50s.) London: W. B. Saunders. 1949.

A symposium of the latest approved methods of treatment.

Pharmacopoeia of the University College Hospital, 1949. Edited by T. D. Whittet, Ph.C., D.B.A. (Pp. 147. 7s. 6d. Shrewsbury: Wilding. 1949.

Extensively revised.

Atomic Energy Year Book. Edited by J. Tutin, D.Sc. (Pp. 237 21s.) London: Temple Press. 1949.

Contains sections on the radioactive isotopes.

Cornell Conferences on Therapy. Edited by H. Gold, M.D. and others. Vol. 3. (Pp. 337. 17s. 6d.) London: Macmillan 1948.

Verbatim reports of fifteen conferences at the Cornell Medical College.

Symposium de Hematologia y Hemoterapia, 1948. By J. Guasi and others. (Pp. 522. No price.) Madrid: "Miguel Servet." 1948. The Spanish text is provided with summaries in English.

The Dentists Register, 1949. Issued by the Dental Board of the United Kingdom. (18s.) London: Constable. 1949.

Transactions of the Third American Congress on Obstetrics and Gynecology. Edited by G. W. Kosmak, M.D., and N. Rutherford, M.D. (Pp. 412. \$9.00.) Oregon: The Western Journal of Surgery Publishing Company. 1949.

Full proceedings of the 1947 Congress.

Public and Personal Hygiene. By F. A. E. Crew, M.D., D.Sc., Ph.D., D.I.H., F.R.C.P.Ed., F.R.S. (Pp. 128. 2s. 5½d.) London: The St. John Ambulance Association. 1949.

Twelve lectures for laymen.

Hints on Prescribing Under the National Health Service Act. By J. B. Primmer, M.B., Ch.B., D.P.H., J.P. (Pp. 51. 3s. 6d.) London: Research Books. 1949.

A short book of prescriptions.

The Mentally Ill in America. By A. Deutsch. 2nd ed. (Pp. 555. 30s.) London: Geoffrey Cumberlege. 1949.

History of the care and treatment of mental patients since colonial times.

The Midwife's Text-book. By R. W. Johnstone, C.B.E., M.A., M.D., F.R.C.S.Ed., M.R.C.P.Ed., F.R.C.O.G., F.R.S.Ed. 4th ed. (Pp. 400. 20s.) London: Adam and Charles Black. 1949.

Further revision has been undertaken in this edition.

The Medical Register, 1949. Issued under the direction of the General Council of Medical Education and Registration of the United Kingdom. (43s.) London: Constable. 1949.

Now published in two volumes for convenient reference.

SURGEONS IN RESIDENCE

New Development at Lincoln's Inn Fields

The President and the Council of the Royal College of Surgeons have for some years now been following a policy of providing facilities and amenities for young surgeons, particularly those from the Commonwealth, the U.S.A., and other countries, who come to Britain for advanced study. The need for residential accommodation was obvious if graduates were to be able to make the fullest use of the library, museums, and laboratories of the College and at the same time have the advantages of collegiate life. The importance of providing a collegiate centre for post-graduate students has often been stressed by Lord Aebbi-Johnson. A step towards the creation of such a centre was taken on May 2, when the first post-graduate students were installed in new residential quarters immediately adjoining the College.

The two houses used for this purpose are Nos 44 and 45, Lincoln's Inn Fields. They are next to the main buildings of the College, the precinct of which has been extended to incorporate them. They provide accommodation for 12 students, with separate bedrooms, and include two common-rooms and a study room. The ground floor of No. 44 is occupied by a committee-room, the postgraduate education office, and other administrative offices. The rooms have been furnished with an eye to both taste and comfort, and offer accommodation far superior to that generally available to students. Indeed the difficulties encountered by post-graduate students in finding any kind of suitable accommodation in London nowadays are well known. Some fine paintings have been hung in the common-rooms, one of which also accommodates a handsome bookcase, formerly the property of Sir John Bland-Sutton. The three illustrations here reproduced are of his particular common-room, a typical bedroom, and a general view from Lincoln's Inn Fields, showing the relation of the two houses to the College itself.

Among the first to take up residence are students from Australia and New Zealand, Canada, South Africa, Ireland, and English provincial centres. The hostel will enable its residents to make informal contact with their teachers, whom they might otherwise meet only in the lecture theatre. The College club in the main building will now allow members and residents to unch and dine together.

Architecturally the houses are interesting. No. 44, built originally in 1638 and rebuilt in 1700, has a fine oak staircase. During the process of redecoration before the opening of the residential quarters the contractors discovered (having previously been warned of its possible existence) a fine painting occupying the ceiling at the top of the staircase. This painting, by Sir James Thornhill (1675-1734) or one of his pupils, has been carefully restored. Thornhill, perhaps best remembered for his paintings at Greenwich Hospital, was the father-in-law of William Hogarth and a great-nephew of Thomas Sydenham. The latter was responsible for launching him on his artistic career, for when Thornhill was sent to London by his impoverished parents Sydenham apprenticed him to Thomas Highmore, sergeant-painter to William III and cousin of Nathaniel Highmore, remembered for his description of the maxillary antrum.

The residents of Nos 44 and 45 will for the most part be studying for the primary or final Fellowship, but accommodation is equally open to more senior students. The provision of this new accommodation sees the completion of the first stage in the larger scheme of which the Nuffield College of Surgical Sciences will be the ultimate development. The first warden to be appointed is Mr R J Last, lecturer in anatomy to the College.

It is hoped that those who have the privilege of living in the College will be imbued with something of the spirit of the collegiate life of the older universities, and that they will meet the leading teachers of Great Britain and distinguished visitors from other countries. Thus they will make contacts which will be valued throughout their lives.

SATURDAY MAY 21 1949

THE AMENDING BILL

When the Negotiating Committee met the Minister of Health in November, 1947, one of the matters it drew his attention to was the obscurity of the Act in relation to partnership agreements. The wording of the relevant Section was so ambiguous that no one, not even Mr. Bevan himself, knew what it meant. But at that time he was intransigent and said that the interpretation of this Section would have to be made in the Courts. The Negotiating Committee presented the Minister with a detailed analysis of the consequences that might flow from the various interpretations of Section 35 of the N.H.S. Act of 1946, and the Minister finally had to acknowledge the justice of the Negotiating Committee's contention and appointed the Slade Committee to report on the position and make recommendations. The Amending Bill promised by the Minister a year ago and now laid before Parliament includes the recommendations of the Slade Committee and adds a Clause on agreements with medical assistants. Clause 12 of the Bill provides for arbitration in case of dispute about remuneration or conditions of service for those working in the National Health Service. Any difference or dispute will be regarded as a trade dispute within the meaning of the Industrial Courts Act of 1919 and under this the Minister of Labour and National Service has power to refer matters for settlement by arbitration.

In the early months of last year the B.M.A. conducted a campaign against the introduction of a whole-time salaried medical service, which under the present Act would have been possible through the issue of Regulations. It did not accept the assurance of the Minister that this was not the Government's intention, knowing that what one Minister said would not be binding on any other Minister. Mr. Bevan once more bowed before the storm and promised to introduce an Amending Act that would safeguard this position. His promise is now fulfilled in Clauses 10 and 11 of the Amending Bill. Subsequently the Minister agreed to include in the Amending Bill a provision that executive councils should have the right to elect their own chairmen, that the professional member of a tribunal should be one of a panel of persons with suitable experience, and that power should be given to the executive councils to cover the costs of local medical committees by the deduction from practitioners' remuneration of a small sum to meet this. These promises have also been met by appropriate Clauses in the Bill.

The medical profession will be relieved that at last a Bill has been introduced which gives statutory protection against the introduction of a whole-time salaried service and that the ambiguities of partnership agreements have been resolved. Partners who have not joined the Service may enter now and receive compensation for the loss of their right to sell the goodwill of their practices.

There were, however, many more matters which the B.M.A. wished to have included in the Amending Bill, and these were listed in the *Supplement* of April 2 this year. What is disturbing is not so much that nearly all these points have been omitted from the Bill as that the Minister has failed to fulfil his promise to discuss their inclusion with the medical profession. To begin with, the Minister said: "There has not yet been time to work out the actual wording of the new measure, and when he does so the Minister will welcome the help of the profession." In spite of his promise the B.M.A. did not know what were the contents of the Bill until it was published at the end of last week. On May 4 last year Sir William Douglas, Secretary to the Minister, wrote as follows to the Secretary of the B.M.A.: "You will remember that when the Minister saw representatives of the Association recently he said that he hoped that he would have the profession's help when he came to the task of settling the contents of the Amending Bill. . . . In addition, as you are aware, we are also most anxious to begin discussions as soon as possible on the other matters which are still outstanding." On May 25 last year representatives of the B.M.A. met the Minister and on the following day were informed by Sir William Douglas of some of the points which the Minister had agreed to include in the Amending Bill. Sir William Douglas stated that it was "inevitable that there will be found other matters on which adjustment is needed in a measure of this magnitude." He went on to say that it would be necessary to limit the Amending Bill so that it could be passed quickly in order to alleviate the anxiety of those in partnership. As there has been a delay of a year in producing the Bill there has clearly been ample time for the discussion of its contents, but no such discussion has been held since May, 1948. The Secretary of the B.M.A. in November last year asked the Ministry of Health when the Association might be given the opportunity of examining in draft the proposed clauses of the N.H.S. Amending Bill—asked Sir William Douglas, in other words, when it was proposed to fulfil the promises made by Mr. Bevan a year ago. Sir William Douglas replied that it was not usual for the actual drafts of clauses to be discussed except within the Government Departments concerned, and added, "But we hope very shortly to discuss with the B.M.A.—or rather with the Negotiating Committee, I suppose—the proper effect and content of any new legislation on this subject." Mr. Bevan, in reply to a question put by Sir Henry Morris-Jones last December, observed: "This matter of an Amending Bill has been under discussion with the representatives of the medical profession, and when full agreement has been reached—or when full agreement has not been reached—then the Bill will be presented to the House." As the medical profession has, since this statement was made, been given no opportunity to agree or disagree, Mr. Bevan's

observation was pointless. He has again committed a breach of trust with a profession that has loyally collaborated with the Government in operating a Service full of imperfections.

There is no need here to enumerate once more the many matters the B.M.A. had hoped to see included in the Amending Bill. From the point of view of the general practitioner one of the most important of these was the need for statutory confirmation of the Minister's written promise that in areas not closed automatic consent should be given to the practitioner's choice of his partner or assistant. Unless this statutory confirmation is given it will still be possible for the Medical Practices Committee to put a practitioner in the position of having to accept a partner chosen by it. Another matter of importance not only to practitioners, but to patients also, which the B.M.A. wished to have included in the Amending Bill was the right of private patients, who incidentally contribute much to the cost of the Health Service, to obtain drugs and appliances at the public expense. It is most regrettable that in the Amending Bill the Minister has refused to recognize representative specialist staff committees which would have analogous functions to those of the statutorily recognized local medical committees. It is regrettable, too, that boards of governors and hospital management committees are not to be trusted to elect their own chairmen, although this right has been given to local executive councils. The farce continues of allowing the foreign visitor to obtain free of charge medical services to the cost of which he contributes exactly nothing; the obvious course is that such a visitor should be treated as a private patient, and the Act specifically provides for private treatment by medical men in the Service.

The Minister of Health may, of course, argue that an Amending Bill at this stage should be free of controversial matters so that it may be passed quickly, or at least before the end of the life of the present Government. The medical profession, while approving in general of the present Bill, cannot fail to be disquieted by important omissions from it and will no doubt press for a further amending measure drawn up after proper and full consultation with representatives of the organized profession.

JENNER AND VACCINATION

The story which began with the birth of Jenner two hundred years ago is not yet complete. Dr. E. Ashworth Underwood recalls the early part in the opening pages of this issue. Since Jenner first put his theory to the test the facts accumulated about vaccination are voluminous, but the conclusions to be drawn from them are imprecise, for no controlled experiment has ever been carried out. Furthermore, as Professor Greenwood has written, "The use of this instrument (vaccination) has been one of the factors, but not the sole, perhaps not the most important, factor in modifying the epidemiological history of smallpox during the last hundred years."¹

Jenner published in 1798 the results of his early experiments. His ideas were quickly accepted both in this country and abroad. Even before the end of 1799 many hundreds of Londoners had been vaccinated, and by 1825 it is believed that nearly half the children born in the large towns were being vaccinated. The first Vaccination Act was passed in 1840, seventeen years after Jenner's death. This empowered Boards of Guardians to vaccinate persons free of charge. In 1853 vaccination was made compulsory. The first relaxation of compulsion was contained in the amending Act of 1898, and this was taken a stage further in the Act of 1907: both Acts allowed for conscientious objection. The Local Government Act of 1929 put an end to Boards of Guardians, and their vaccination duties were transferred to local health authorities, though many of these authorities delegated their powers to the public assistance committees, which inherited the Poor Law. The National Health Service Act, 1946, repealed the law requiring vaccination to be compulsory, but left local health authorities with the duty of carrying out vaccination and revaccination both as part of the ordinary child-welfare service and as an emergency public health service for the control of epidemics.

Between 1854 and 1905 the proportion of infants vaccinated was seldom below 70% of those born. By 1914 the figure had fallen below 50%, and for some years before the end of compulsory vaccination in 1948 only about one-third of the infants born in this country were being vaccinated. This decline was not due to the success of anti-vaccination campaigns, though the distaste which some have felt for everything connected with the idea of vaccination has been responsible for a controversy that has simmered for more than one hundred years and boiled over on several occasions. During this time the opposition to vaccination was far from being negligible in quality. For instance, Creighton, who called vaccination "a grotesque superstition," has been described as the most learned medical scholar of the nineteenth century. Bernard Shaw's remark about "an amazing empirical stunt" is the sort of half-truth which irritates more than it enlightens. Most probably the decline in vaccination was due to the freedom of this country after 1902 from epidemics of variola major and to the increasing awareness among the public that vaccination itself was not always a harmless procedure.

Though improved living conditions and advances in medical and sanitary science must have played an important part in reducing the incidence and mortality of smallpox, the discovery of vaccination will remain one of the great achievements in the history of preventive medicine. Professor Greenwood has stated that it can safely be inferred from the evidence that Jenner was directly or indirectly the means of saving many hundreds of thousands of lives.² In England and Wales the death rate per million from smallpox in 1856-60 was 180: in 1871-5 (there was a severe epidemic in 1872) the rate was 392; and in 1896-1900 it was 7. Only 28 persons died from smallpox between 1933-46, and among the fatal cases there was no infant under one year of age. Killick Millard³ has pointed out that in the same period there were 51 deaths of infants from the complications of vaccination.

¹ *J. R. statist. Soc.*, 1930, 93, 233.

² *Epidemics and Crowd Diseases*, 1935, London.

³ *British Medical Journal*, 1948, 2, 107.

⁴ *Ibid.*, *Suppl.*, 1935, 1, 282.

The effect of vaccination on the incidence of smallpox is difficult to assess. The B.M.A. Committee on Immunization, including Vaccination,⁴ which reported in 1935, considered that the relatively incomplete immunity which was a result of the vaccination of most of the infants born in this country up to the beginning of the present century was usually sufficient to limit the volume of outbreaks. It would certainly be foolish to suggest that we have seen the end of deadly smallpox in this country, but those who would accuse the Government of rashness in putting a stop to compulsory vaccination are probably in a minority. Eleven years before the National Health Service Act was passed Greenwood wrote, "Provided we keep our powder dry, that we have always available a completely sufficient supply of potent lymph, I think we may view the passing of even nominally compulsory vaccination with equanimity."²

The responsibility for persuading parents that vaccination of infants is still advisable rests with general practitioners and local health authorities. If there is danger of an epidemic the success of the steps taken by local authorities to limit its spread will depend very much on the way they approach the public. A population which is kept well informed will be much more amenable to advice than one which has been left in the dark. The public should be given more information about the importance of revaccination, for belief that vaccination in infancy protects throughout life is still quite common. Since Jenner's day opinion has changed about the duration of the immunity conferred by vaccination, and no dogmatic ruling can be given. It is usual now for members of the Forces to be revaccinated every two years when serving abroad. The methods which port health and local authorities use to control the spread of smallpox have been well illustrated during the last few weeks since the arrival in the Port of London of the s.s. *Mooltan* on the day after the death of a passenger from smallpox. The action taken seems to have been effective, though one case of smallpox notified in a rural area on May 7 may have some connexion (as yet unexplained) with the outbreak among the *Mooltan's* passengers.

Smallpox has been a dreaded disease for hundreds of years, and the greatest encouragement to vaccination has been fear. There is still no specific treatment for the disease, but it seems probable that some chemotherapeutic or antibiotic substance will be found which will attack the variola virus *in vivo*.

RADIOTHERAPY

It is just over twenty years since the National Radium Commission took charge of the radium which the National Radium Trust bought for the nation with part of the fund collected in thanksgiving for the recovery of George V from a serious illness. By the N.H.S. Act the Minister dissolved the National Radium Commission, and by the Amending Bill Section 3 of the Cancer Act, 1939, empowering the Minister to lend money to the Trust, will cease to have effect. To the Commission must be given the credit for the wise development of radiotherapeutic services throughout Britain. One of the results of its activities is that all patients requiring radiotherapeutic treatment for cancer are

within reach of a centre where radium and x-ray apparatus are under the control of a skilled radiotherapist and where adequate treatment and follow-up records are kept.

One of the last acts of the National Radium Commission was to approve publication of Dr. Margaret Tod's report¹ on "the extent to which cancer patients in Great Britain receive radiotherapy." The report is in three parts: the first is an attempt to assess the number of patients requiring radiotherapy, the second a statement on the number of patients treated in all hospitals which reported to the National Radium Commission, and the third a comparison of the two previous figures with the object of assessing how the needs of the population were met. In order to determine the number of patients requiring radiotherapy it is necessary first to estimate the incidence of cancer and, secondly, the proportion of patients requiring radiotherapy according to the site of the growth. Cancer registration figures from Liverpool, Oxford, and Connecticut show that the cancer incidence appears to be 2,000-2,350 per million. Dr. Tod also uses an indirect method of calculating the incidence of cancer from combined death rates and survival rates: she obtained the data for this from a table of deaths from cancer in 1944 supplied by Dr. Percy Stocks (the death rate being 1,748 per million); from the estimated rates of survival of patients in Manchester, New York, and Liverpool with cancer of accessible sites; and from Sholto Mackenzie's² figures of patients with untreated cancer of various types. The incidence is in this way assessed at 2,122 per million. This figure is lower than the registered rate for Oxford but similar to that for the Liverpool area. There is good reason to think that these registered rates are low, and some unpublished figures from Edinburgh suggest that the incidence may be about 2,500 per million. Accuracy of death registration by doctors is not as great as accuracy of cancer registration by those particularly interested.

The need of patients for radiotherapy depends largely on the site affected. Dr. Tod estimates the number of cases treatable by radiotherapy from the rates of incidence and from figures supplied by radiotherapists. The overall figure is 40%, but it varies from 85% for a group including lip, skin, mouth, and uterus, to 0% for the group including stomach, intestine, liver, etc. The total number of patients requiring radiotherapy per million of the population is 840; this is higher than the figure Paterson³ calculated in 1942, but, as he suggests, it is probably more accurate. The numbers of patients treated in various regions show that the proportion of treatable cases actually treated is about 77%—being 95% in London. The fact that the figure is 127% for one region and 11% for another suggests that the estimated incidence of cancer may be about 30% too low, but there seems no doubt that at least 40,000 new patients require radiotherapy each year and that about 9,000 of them do not get it. This takes no account of radiotherapy for non-malignant conditions and of the retreatment of certain cases; both these needs must be

¹ *An Inquiry into the Extent to which Cancer Patients in Great Britain Receive Radiotherapy*, 1949, Altrincham, price 3s. 6d. net.

² *An Inquiry into the Extent to which Cancer Patients Receive Treatment*, 1939. Reports on Public Health and Medical Subjects, No. 89. London: H.M.S.O.

³ *Publ. Hlth, Lond.*, 1936, 50.

considered in assessing the requirements in any region. Informative tables are included in Dr. Tod's report showing the facilities at present in existence in England, Wales, and Scotland, and of the cases treated in clinics in this country and in a few abroad. It is emphasized that centralization of treatment, avoiding the inefficient dispersal of facilities, should be the aim, and that no centre treating less than 800 new cases of cancer annually should be encouraged.

The estimate provided by this report of the radiotherapeutic needs of the country must provide a basis for arrangements to be made in the future. The distribution of both apparatus and beds is still very uneven. The less well equipped areas should be brought up to the standard of the better equipped. In this connexion it must be remembered that the safe use of radiotherapy apparatus is expensive, and it might be desirable for the Ministry to allot funds for radiotherapy direct. Budgeting for heavy expenditure by hospitals which already have difficulties in finding ends meet may retard development of radiotherapy departments. There is no doubt that many patients alive now would be dead but for the fact that they have been treated by radiation, and no doubt that most cases of cancer die of their cancer in spite of all that can be done by surgery, radiation, and chemotherapy. At present only surgery and radiation can be considered curative: other methods do not cause complete disappearance of cancer. What, then, is to be done for the large groups of patients (with, for instance, cancer of the stomach and lungs) in whom cures are very few? Further development of radiotherapeutic methods and close liaison between radiotherapist, surgeon, and physician are essential if treatment is to be given to all the 40,000 new cases of cancer which need radiotherapy during the course of each year.

STREPTOMYCIN IN TUBERCULOSIS

Workers in Switzerland have made a notable contribution to the literature on the streptomycin treatment of tuberculosis in a massive and profusely illustrated volume¹ containing 20 papers by various authors, of which four are on the theoretical or experimental aspects of the subject and the remainder on the results of treatment in various forms of the disease. Two are on the treatment of meningitis: Löffler and Piotti treated 13 cases by conventional methods with only three ultimately successful results. Dolivo and Rossi, on the other hand, after failure in eight out of nine cases given the usual dosage, treated 13 further patients with much smaller doses in a prolonged but intermittent course combined in the later cases with a sulphone; in six of these patients the result was good. This modification evidently deserves close attention. The writers emphasize the necessity for early diagnosis, without which treatment is liable to fail—even though life is prolonged—owing to the development of cerebral lesions which were never seen when the disease was fatal in about three weeks. These, and in particular the arterial lesions and their consequences, are well described by Zollinger.

The volume reveals a general tendency to regard the indications for streptomycin in other forms of tuberculosis as rather more numerous than is generally agreed: the

editors in their introductory chapter give five absolute indications, which include all febrile infections in infants and certain categories of urogenital disease, nine relative indications, and four requiring further study. They mention only four conditions in which treatment is definitely not indicated. In advanced renal disease streptomycin is recognized as being to a large extent only palliative: nothing is clearer than that bacilli in massive caseous lesions, wherever situated, cannot successfully be attacked. There are three papers on the treatment of pulmonary disease, in one of which Tanner commends the instillation of streptomycin solutions into cavities undergoing Monaldi drainage. Russi also advocates local treatment for disease of the middle ear. The whole work is profusely illustrated by excellent photographs and a number of coloured plates.

Whether and when to use streptomycin in chronic pulmonary disease is likely to remain the most difficult question. Levine and his colleagues² are very emphatic that it should be used only as part of a concerted plan for the entire conduct of a case—as an adjunct, in fact, to other forms of treatment. Only one course is likely to be of benefit, and if this is given at too early a stage and the disease again becomes active later a valuable resource has been lost. They themselves have used it only in cases with extensive and spreading lesions, and with the sole object of arresting extension and so improving the general condition for the time being that appropriate surgical treatment became safe and feasible. The choice of such cases must always be difficult, but the principle that streptomycin should not be given alone, merely in the hope that it may perhaps do some good independently of other treatment, is clear enough and worthy of serious consideration.

NECROPSIES AND TUBERCULOUS INFECTION

The risk of contracting tuberculosis at post-mortem examinations, both for participants and onlookers, may have been underestimated. At Lund University, as elsewhere in Sweden, medical students attend a general pathology course, which includes necropsies on tuberculous cases, before they start their regular clinical work. Prior to wholesale B.C.G. vaccination many of the students were tuberculin-negative on entry, and the Students' Tuberculosis Bureau, by analysing figures of conversions from tuberculin-negative to positive and of tuberculosis morbidity, was able to show an association between these and attendance at the pathology course, quite apart from any association with the period of clinical training.^{1,2} Direct bacteriological examinations showed that many objects in the post-mortem room were contaminated 24 hours after examination of the body of a tuberculous patient, in spite of routine cleaning. Following the introduction of stringent precautions at such necropsies there was a decrease in the tuberculin-test conversion rate among the students attending the pathology course. Among these precautions were exclusion of students from actual participation in the post-mortem examinations of known tuberculosis cases, the fitting out of a special necropsy room with improved cleaning facilities, and injection of formalin into the pulmonary artery of the cadaver.

More recent evidence from the University of Rochester medical school in the U.S.A. amplifies the Swedish experience.³ At this medical school, where there was a high tuberculin-test conversion rate and a high tuberculin-testing attack rate among the students, tuberculin-testing re-

Medical Students

that most of their primary infections occurred during the second year, when a 20-weeks pathology course was taken, but before the practical clinical work was started. All these students had opportunities for coming into frequent contact with tuberculous material. At the end of the first year an average of 54% of the students were positive reactors, and the figure rose to 92% at the end of the second year. After exclusion of second-year students from participation in the necropsies of tuberculous cases and from the handling of tuberculous tissues it was found that on an average 36% of the students were positive reactors at the end of the first year, 39% at the end of the second, and 52% at the end of the fourth year.

In British medical schools the students usually do not attend post-mortem examinations regularly until their clinical course has begun, and it would be difficult to assess the separate danger of developing a tuberculous infection as a result of taking an active part at such examinations. However, bacterial spread around the cadaver and post-mortem table should be investigated in order to identify the most risky procedures. Meantime, though the Scandinavian and American results do not constitute proof, they provide grounds for revising the general opinion that the rapid conversion of medical students from tuberculin-negative to tuberculin-positive during their hospital studies, as well as their liability to contract tuberculosis, is solely the result of their contact with living patients. Tuberculous necropsy material must now be regarded as a source of infection, and all possible steps should be taken to reduce the risks to which medical students may be exposed. Few medical schools in this country can claim to conduct post-mortem examinations according to a rigorously strict hygienic routine. The adoption of operating-theatre processes (partially in reverse) should be considered: for the participants, masks (and, of course, gloves) and no smoking on the job; for the onlookers, a glass screen, care in the display of tuberculous viscera when removed from the body, and the application of disinfectants to supplement the customary hosing down with water afterwards. Such precautions should be supported by periodic x-ray examination of the students and by tuberculin-testing—procedures which still await full application in some medical schools.⁴

Quite recently a new danger arising from tuberculous tissues has been reported, this time involving a large section of the public. There is little meat for pets in household scraps, and uncooked beef from tuberculous carcasses unfit for human consumption is finding its way from knackers' yards to pet-food stores.⁵ The unsuspecting or uninformed purchaser may contaminate her kitchen and endanger the health of her family. Moreover, cats and dogs can contract tuberculosis from eating raw infected meat. The National Veterinary Medical Association has given warning of these risks and has suggested that all meat sold at pet-food stores should be sterilized by boiling before sale.⁶ In Birmingham the Corporation has obtained powers to enforce sterilization.

CONTROL OF PARADOXICAL RESPIRATION

The dangers of making a wide opening through the chest wall into the pleural cavity and the method of overcoming them by inflating the lungs through the trachea were known to Vesalius in 1555,¹ but until recent years—long after successful general surgery had become commonplace—surgery in the open thorax was a dangerous procedure attempted only by the venturesome. Brauer² ensured adequate filling of the collapsed lung by making the patient breathe gases under positive pressure—so-called "positive-

pressure breathing"—while Meltzer and Auer³ and later Elsberg⁴ solved the problem of paradoxical respiration by continuous intratracheal insufflation. This so reduced the alveolar carbon dioxide that spontaneous respiratory movements practically ceased. With the latter method the patient remains adequately oxygenated in spite of the apnoea, and in fact recent work^{5,6} shows that oxygen will diffuse through the length of the tracheobronchial tree and into the blood (thus maintaining life) provided the nitrogen is first removed from the upper respiratory tract.

Since the beginning of this century, when thoracic surgery was in its infancy, the methods of maintaining adequate respiratory exchange by . . . breathing and intratracheal insufflation . . . improved, and anaesthetic machines permitting a very accurate control of positive pressure were developed from Brauer's early pattern. With the introduction of cyclopropane and of the closed-circuit apparatus it was soon discovered how easily apnoea could be induced by a little hyperventilation. This made possible intermittent inflation of the lungs and provided an excellent method of avoiding paradoxical respiration and its evils. Tracheal insufflation soon gave way to this new technique, which became known as "controlled respiration" and is now the method of choice in this country for making an open pneumothorax safe. Filling the lung no longer depends on diaphragmatic movement; paradoxical respiration does not occur, and both lungs may be inflated equally. Positive-pressure breathing and controlled respiration both have their advocates,^{7,8} and the fact that both have remained in use for so many years shows that either method, in the hands of experts, will give good results. Recent reports from anaesthetists in this country^{9,10} confirm the efficacy and safety of controlled respiration, while good results are claimed for positive-pressure breathing, particularly in the U.S.A., in major operations such as lobectomy and pneumonectomy.⁷

Whichever method is used, there is much interference with the normal processes of respiration: in the case of controlled respiration ventilation is no longer dependent on the metabolism of the patient but on the judgment of the anaesthetist; and with pressure breathing the lungs cannot empty properly and the whole physical mechanism of respiration is upset. Neither method should be attempted except by skilled anaesthetists.

SPECIALISTS' CONTRACTS

During the past few weeks the Central Consultants and Specialists Committee has been considering the Ministry's proposals about terms of service for hospital medical staff in the light of the views received from the periphery through the Regional Consultants Committees. The committee has now submitted to the Joint Committee with the Royal Colleges a statement of the points on which it wishes representations to be made to the Ministry. A further announcement will be made as soon as the negotiations which are about to take place with the Ministry are completed. In the meantime consultants and specialists are again advised not to sign permanent contracts, if they are invited to do so, before the final terms have been published and approved by the profession.

A mirror reflects the operative field into the CPS Emitron camera, which is remotely controlled

TELEVISED OPERATIONS

Demonstration at Guy's Hospital

What is said to be the first permanent installation of television equipment for medical teaching purposes was demonstrated at Guy's Hospital last week. At present four viewing sets are installed at the hospital—one in the surgeons' room, one in the library and exhibition room, and two in one of the lecture theatres. In groups round each receiver some 30 or 40 persons may view an operation from a vantage point "as good as that of the surgeon himself".

The apparatus has been designed by Electrical and Musical Industries, Ltd. of Hayes, Middlesex, in collaboration with the Department of Surgery at Guy's. The viewing sets are standard H.M.V. models, with a 15 in. (37.5-cm.) emicope tube, slightly modified to work on signals received by cable. The equipment delivers television signals of the standard wave form used by the London television service of the B.B.C., but a higher definition can be made available when required. There is provision for a demonstrator to supplement the surgeon's comments or alternatively to be responsible for the whole description of the operation. This demonstrator may be stationed in one of the viewing rooms, and he is able to select at will the most suitable size of field as the operation progresses.

It is intended to build up a repertoire of standard operations suitable for television and to invite surgeons from hospitals throughout the country to watch the televised operations and comment on the installation. Certain types of operation, such as cervical sympathectomy, are not considered suitable for television as yet, although an image can be obtained. The installation will be mainly for the benefit of postgraduate students and visiting surgeons.

When the camera is mounted above the table a picture is given looking directly down on the operation site, as opposed to the oblique view from the galleries. It is, of course, a disadvantage that transmission cannot take place in colour, but the technical problems of picking out in monochrome the different shades of tissue are being surmounted successfully. Subject to this reservation with regard to colour—which no doubt will be overcome in time—the picture obtained is very good and the definition is such that the procedures can be clearly followed. Special precautions have been taken to prevent interference from other electrical apparatus in the hospital.

For those interested in television a few other technical details may be added. Transmission is by cable, so that there is no question of an operation being watched by lay people or their home receivers. The camera is completely enclosed and is built in, together with a microphone for the surgeon's sound commentary, as an integral part of the shadowless light unit over the operating table. The whole assembly can be rotated through 60 degrees for operation on an inclined table or moved on an overhead track.

A surface reflecting mirror is mounted on the centre of the lamp and at 45 degrees to its axis, so that a view of the operation along the axis of the lamp is presented to the camera. The camera, which requires no special lighting, has a cable which, with the lighting, sound and control cables is taken through to a control point in a room alongside the theatre. The whole apparatus in the theatre has been designed so that it may easily be kept clean and sterile (Fig. 1). In the control room the unit is operated by a hospital technician, who by means of a monitor unit can watch the picture. In this room also the lens unit in the camera is operated, with a choice of three magnifications and the surgeon in the which, with the lighting, sound, and control room which picture he wishes shown whether an overall field of approximately 20×35 in. (50×87.5 cm.) an approximately life-size reproduction, or a magnified close up of an area of about 5×6 in. (12.5×15 cm.)

The televised operation has an advantage in spontaneity over the film, but the latter, of course, can be edited whereas the former cannot. The two methods therefore are complementary, and it is considered that television may become important and useful in medical teaching. Certainly the spectators can see more detail in greater comfort than is ever possible in a crowded theatre. The possibilities of television as an aid to medical instruction have long been a matter for conjecture. On a few special occasions in America television has been temporarily installed in an operating theatre to enable groups of surgeons to watch a particular operation, but the installation at Guy's is the first properly engineered permanent equipment, and this was the first occasion on which operations have ever been televised in Europe.

Students and nurses watch the operation on the television screen

Correspondence

An Unfortunate Precedent

SIR,—Since its foundation some four centuries ago the Royal College of Physicians, through its Comitia, has been consulted by all British Governments on all important problems of public health and medical teaching and practice. The appointment of its actual president to the Awards Committee is thus not an "unfortunate precedent" but a justified historical custom. To reproach Lord Moran because he has been entrusted with this duty and to call the officers of the College, distinguished scientists and upright men, "henchmen" of the President and "inner cabal" of the College is to attack the dignity of that great institution whose role in the history of medicine—not only of British medicine—has been preponderant. I am convinced that most Fellows will resent this attack, whether they have accepted the Health Service or whether, like myself, they wish to maintain the independence and the freedom of medicine. It is not a question of party.

I do not think Dr. C. B. Heald (May 7, p. 819) has accurately described the inner workings of the College, because on all important matters there are lively discussions in Comitia. The "recommendations of the Council" bear usually on secondary matters, and, if they are accepted mechanically, this is due to the fact that the Council has thoroughly studied these questions, whereas the majority of the Fellows come totally unprepared. If Dr. Heald had made his interesting suggestions in committee instead of resorting to the medical press he could be assured of the support of many of his colleagues, and the thanks of all, for rendering the meeting of the Fellows as lively as the dinner that follows it.

In the course of its long history the senior College has faced all medical problems, adapting its policy to changing conditions with an elasticity which is certainly not "archaic." In our days the problems are more acute because, as individual physicians, we have concentrated too much on our test-tubes and microscopes and have neglected social medicine. The task of the College is thus more difficult than it was in the days of Linacre, when it had simply to uphold the Hippocratic and Galenic doctrines against Arab scholasticism, or, as later, to struggle with the University of Oxford for the programme of medical teaching, to consider the seaworthiness of the physicians of the Elizabethan fleet, or to legislate on variolization or hypnotism.

However, the College has to take a stand and contribute to the adaptation of medical practice to our new highly industrialized and mechanized society. History shows that human groups that have not responded to the challenge of changing environment have died out, and the senior College, founded by the most brilliant intellects of the Renaissance and built up stone by stone in the course of five centuries by men of outstanding brain and heart, cannot die out. As in the course of centuries the College changes its mode of action, abandoning the academic ivory tower, it has to come more into the open social struggle. It may be difficult in these conditions to preserve its ancient dignity, but it is not a good thing, not only for British medicine but for world medicine, if in these disturbed times of political and economic passions the role of this solid bulwark of the highest medical standards is made more difficult. The laws of history, little known and even less heeded, warn us against any such action.—I am, etc.,

London, W 1

A. P. CAWADIAS.

Research in Renal Disease

SIR—While Sir Henry Cohen, as reported in the *Journal* of April 2 (p. 587), grudgingly admits that there is some justification for a man pursuing research in renal disease, it would be interesting to learn upon what grounds he so confidently asserts that there can be no justification for a man confining his practice of medicine to the kidneys. I do not know to what extent Sir Henry's personal experience of this kind of practice entitles

him to make this pronouncement, but I can assure him that he is in error.

Anyone who endeavours to achieve such proficiency in treating patients suffering from renal disease as current knowledge permits will find that his time is so fully taken up that he has no alternative but eventually to confine his practice to this branch of medicine. Unless he does it is unlikely that he will be able to handle sufficient material to acquire adequate experience; nor will he realize the unceasing attention to detail, even the nature of the detail itself, that is so often necessary if all that is possible is to be done for these patients. He will find it an additional handicap that there is probably no hospital in the country that is suitably organized, staffed, or equipped for obtaining the best results from modern methods of treatment. It must be remembered also that nephrology can be practised effectively without at the same time engaging in research for standardized methods of treatment are not successful in a minority of renal disorders.

It is singular that Sir Henry should have selected the kidneys and none of the established specialties for his strictures. The accusation so frequently levelled against the specialist that he is not sufficiently in contact with general medicine can hardly be maintained in respect of the kidneys, where the relationship with other vital organs and processes is too intimate and too obvious to be ignored. But the recognition of nephrology as one of the major medical specialties in no sense implies that we must lose the valuable contributions to the knowledge of renal disease that the general physician may confidently be expected to make in the future as in the past. There is more than enough room in medicine for all degrees of emphasis in the study of, and practice in, renal disorders.

It is common knowledge that patients suffering from renal disease often come under the care of those who have made no serious study of their problems and who, indeed, are not even interested in them. Patients are frequently "written off" on sight or after a more or less perfunctory investigation, and are hustled out of hospital without systematic provision for their future welfare. This attitude of defeatism is particularly dangerous in undergraduate teaching hospitals, for it is accepted by students and forms the basis of their outlook on renal disease.

What is needed is the provision of postgraduate university hospitals or institutes for renal disease, adequately federated in the general hospital services and based on departments of renal anatomy, physiology, pharmacology, and clinical and experimental nephrology. These hospitals should eventually staff and work in close liaison with subsidiary renal units in other postgraduate hospitals, in undergraduate teaching hospitals, and in some of the larger non-teaching general and appropriate special hospitals. The need, moreover, is urgent, for the training of the necessary medical, nursing, and technical staffs must inevitably take much time. A beginning, however, could be made at once with the establishment of one such centre.

The training of a nephrologist must necessarily be long and arduous. It should include at least six years' postgraduate study, practice, and research in general medicine, and special experience in biochemistry and clinical pathology. I do not believe that the full course could be accomplished in less than eight years after registration.

The problem of renal disease is one of national importance. It concerns the welfare and the lives of a large section of the population, including many young persons. Kidney disease, directly and indirectly, probably causes more deaths in this country every year than cancer, heart disease, or tuberculosis. The training of a sufficient number of competent nephrologists and the provision of adequate facilities for their work are among the most pressing needs in medicine to-day.

In my view Sir Henry has failed to appreciate the magnitude, gravity, and complexity of the problem of renal disease. There is, of course, every justification for those with inclination and aptitude to confine their practice of medicine eventually to the kidneys, and they should be given every encouragement to do so if they find, as most will, that they are thereby enabled to give better service.—I am, etc.,

London, W. 1

A. A. OSMAN.

Thymoma Simulating Laryngeal Diphtheria

SIR.—Dr. Alwyn Griffith (April 30, p. 759) has described an instance of what he interprets as a "thymoma simulating laryngeal diphtheria" in a child aged 4½. His account of the patient suggests to me that this was almost certainly an example of acute myasthenia gravis, and that the child's death was not due to pressure caused by the presence of the tumour.

It is not generally known that an acute form of myasthenia gravis occurs in young children, the leading sign being failure of respiration with cyanosis. The condition described by Dr. Griffith would probably have responded dramatically to an injection of "prostigmin," as it did in two children, aged 4½ and 2, under the care of Dr. W. G. Wyllie at Great Ormond Street Hospital for Sick Children a few years ago. I operated on both these children for thymectomy, and the elder one has been well since; the younger one afterwards died in a relapse of myasthenia because I had failed to remove the whole of the gland.

Dr. Griffith's description does not convince me that the organ found in the mediastinum was really a tumour in the sense of being a neoplasm. It may have been simply a large thymus gland, which would normally be of considerable size at the age of 4. Thymic tumours usually become closely adherent to surrounding structures and show an obvious proliferation of epithelial or reticular cells.—I am, etc.,

London, W.1.

GEOFFREY KEYNES.

Endocrines and Fibro-Adenosis

SIR.—In his interesting paper on this subject (April 30, p. 750) Mr. H. J. B. Atkins ascribes to me opinions which I do not hold, and I would be grateful for the opportunity of correcting this misapprehension. I am quoted as having advocated androgen therapy for fibro-adenosis, "in the hope that this will prevent the onset of cancer" (*British Medical Journal*, 1938, 2, 319)—a view which I have never held, even in the most optimistic moments, much less propagated. What I actually recommended (and I think I was the first to do so) was the routine implantation of testosterone in the wound after a radical mastectomy in cases of breast cancer as a prophylactic against recurrence, and repeated implantations from time to time—a view substantiated by Adair at a meeting of the Section of Surgery, Royal Society of Medicine, on March 23 (reported in the *Journal* of April 9, p. 631), and others.

In spite of this disclaimer, however, I cannot agree with Atkins that testosterone can be actively cancerogenic in cases of fibro-adenosis. Both theoretical considerations and practical experience are to the contrary, and the one case quoted is most likely, in my opinion, coincidental. It is hoped that Atkins's condemnation will not have the effect of depriving patients of the advantage of a hopeful, if temporary, therapeutic agent.—I am, etc.,

London, W.1.

A. A. LOESER.

Diathermy Prong Forceps

SIR.—As the originator of the principle of diathermy haemostats, it is easy to settle the differences between Mr. A. Wilfrid Adams (April 9, p. 631) and Mr. David Aiken (April 30, p. 780). They are both right. In 1924, at the Christie Hospital, Manchester, I first used artery forceps connected by flex to diathermy to seal vessels. From 1932 onwards most of my patients have been connected to diathermy,¹ and two pennyworth of British electricity has done just as well as, and probably better than, four dollars' worth of American catgut. Minute vessels have been closed at a depth of even a foot in the lower abdomen, and a tiny piece of sterile carbon has replaced a ligature, which is always liable to go septic. Haemorrhage, time, and labour have been saved. Wounds have healed better because sepsis has been avoided.

Why the principle has not been more widely used I have never understood. In my long surgical experience, by the use of diathermy I have avoided the tedious tying of millions of ligatures; for example, in a cancer of the breast it is unnecessary to tie more than twelve ligatures, and in a subtotal thyroidectomy five. The technique is easily acquired—far more easily than to learn to drive a motor-car. The simple

harmonious use of one foot and one hand is all that is required. But a full knowledge of the dangers of diathermy and the protection of the patient are essential.

As the method advanced, I used one thin flex which could be attached to many instruments of varying depths and type. Mr. Adams has produced another instrument to his liking, and so will any surgeon who uses the principle. Mr. Aiken came as resident to the Christie Hospital during the war, when I could not have diathermy instruments made for special purposes and had therefore to return to flex attached to any instrument by adhesive or insulating tape. He did a great service by publishing² my principles in an immature form. He is still not aware that adhesive tape, although boiled, will still retain microbes in its depths, and naturally will occasionally become unstuck. That is why attachment by tape, as described in his letter, may become dangerous. And it is far safer, though possibly a little cumbersome, to use an attachment like that of Mr. Adams.—I am, etc.,

Manchester.

A Danger to Public Health

SIR.—The remarks of your correspondent Dr. G. C. F. Ree (April 30, p. 776), on the spread of smallpox prompt me to draw attention to another point which would seem to require attention. Shortly before the importation of smallpox on s.s. *Mooltan* a certain person who in recent months became somewhat of a national character left this country in a mysterious manner. Despite the fact that his picture had been in every newspaper and periodical over a period of weeks, he was able to leave by an unknown route and without the knowledge of police, emigration officials, or customs. This occurred within a reasonably short interval of the disappearance of aircraft in some numbers and by unknown routes from this country without the knowledge of the authorities, and it is reasonable to suppose that the whole of this illegal traffic has not always been and will not always be in one direction.

In view of the fact that the farthest point in the world is now within the incubation period of the major infectious diseases, illegal entry into this country by air creates a grave risk to the public health. It is suggested, therefore, that everyone should co-operate in preventing a continuation of such traffic in the future, and that offences, when detected, will be met by such penalties as to deter people from committing what may appear an adventurous crime but which may have grave and far-reaching consequences.—I am, etc.,

Brit. Bucks

V. O. S. GARTSIDE.

Treatment of Basal-cell Carcinoma

SIR.—I would like to record my appreciation of the excellent paper on the surgical treatment of rodent ulcer by Sir Cecil Wakeley and Mr. Peter Childs (April 30, p. 737). The authors state that there should be no recurrence with adequate surgical excision and recommend that treatment for all rodent ulcers. I think the authors are to be congratulated on the uniform success of their treatment, which is a tribute to the combination of their good judgment and technical skill.

I have no criticism of their recommendation as it applies to lesions on the neck, trunk, and limbs, where wide excision is relatively uncomplicated, and would merely add that many of the superficial rodent ulcers in these sites run a very slow benign course, and elderly, timid patients may be safely treated by irradiation or, if the lesions are very superficial, by freezing with CO₂ snow for two or three minutes.

Apparently rodent ulcers occurring on the face, especially about the temples, the eyes, and the naso-labial folds, are not so readily treated by simple excision as the authors suggest, and many cases of recurrence after surgery have attended dermatological departments and radiotherapy centres. I have seen a considerable number, some of which had relapsed after two excisions and one after three excisions by a competent surgeon. I do not agree with the authors that the extent of excision necessary is readily gauged, and I believe that the extent of some rodent ulcers, with the presence of neighbouring microscopic

nodules, cannot be discerned with the naked eye. It would also appear that the surgical disturbance of tissue balance has a markedly activating effect upon any residual malignant cells, and relapses after incomplete excision usually run a more rapid course.

It should be remembered that towards the end of the nineteenth century the surgical treatment of rodent ulcers of the face had fallen into considerable disrepute, and the expression "noli-me-tangere" had been applied to rodent ulcers and considerable thought had been given to other measures of treatment. Burning-irons of various shapes were used by the surgeons of the London Hospital instead of excision, and the introduction of radium and x-ray treatment was welcomed by the surgeons. In fact Dr. Sequeira was invited to an International Congress of Surgery at Stockholm in 1905 to read a paper on his technique with radium in the treatment of malignant diseases, especially of the skin.

Since that time by far the greater number of rodent ulcers have been treated by dermatologists or radiotherapists. Treatment with the unscreened radium plate, or with x-ray therapy alone or after preliminary curettage, is not tedious, nor as a rule is the reaction at all severe, and the resulting scar is relatively inconspicuous. Many elderly patients are much less bothered by non-operative treatment, and in the sites most suitable for wide excision the results of such treatment are almost uniformly satisfactory. It is admitted that, in any large series of rodent ulcers treated by irradiation, recurrence may account for 5 to 10%. The small squamous-celled lesions are not usually more radio-resistant than the true rodent ulcer.

No doubt some further comment will come from radiotherapists with considerable experience in the treatment of these lesions, but as a dermatologist I think the above remarks are fair comment.—I am, etc.,

London, W.1.

R. T. BRAIN.

Smallpox Contacts

SIR,—I think that the majority of doctors will agree with Dr. G. C. F. Roe's suggestion (April 30, p. 776) that protective vaccination of travellers before leaving any country infected with smallpox would be the surest safeguard against the introduction of variola major to this country.

I was interested in his treatment of contacts by voluntary isolation in the isolation hospital. With a considerable number of contacts arriving from abroad over the past few years, and depending upon the safeguard of timely vaccination, I have relied upon an immediate home visit, with advice and instructions to report immediately any symptoms or signs, however trivial—a complete examination being made only in exceptional cases. I have not interfered with the liberty of the person to pursue his ordinary avocations, believing that smallpox is not infectious unless or until a rash appears. People from affected countries abroad are well aware of the risks of smallpox, and all are anxious to co-operate in every way.

It may be that stricter measures are desirable in congested towns than in rural areas. I feel that the views of other medical officers would be useful.—I am, etc.,

Guildford, Surrey.

J. E. HAINE.

SIR,—From the statement by the Port of London Authority appearing in *The Times* of May 10 about the outbreak of smallpox in the s.s. *Moolan* and the measures taken by this authority, it would appear that the ship was released from quarantine on Sunday, April 3, and the passengers allowed to disperse after full particulars of all destinations had been given and all relevant local authorities had been informed.

Quarantine, as you will agree, is the limitation of the free movement of contacts until it is certain that they have not acquired the disease to which they have been exposed. As it was not until March 31 that it was strongly suspected that this was a case of chicken-pox, I think it was likely to be a case of smallpox. I think for the purpose of quarantine the operative date should be April 1, in which case the ship should not have been released from quarantine until April 16 at the earliest.

I cannot agree with the practice of allowing contacts of a suspected case of Asiatic smallpox to mix freely with the general population, no matter how close the supervision is. It is common knowledge that a very large section of our population

is unvaccinated, and, now that vaccination is no longer compulsory, this unvaccinated population will grow larger. While such a state of affairs exists in this country it is only fair to the public to insist that quarantine be adequate and complete. I feel sure that much of the present anxiety and alarm in the country to-day would not have occurred if the *Moolan* passengers had been kept on board until April 16.—I am, etc.,

Launceston, Cornwall.

L. RICH.

Ankylosing Spondylitis

SIR,—In his letter (April 2, p. 591) under this heading Dr. F. Hernaman-Johnson asks, "Is their sole resort to be the orthopaedic surgeon, who, after all, deals with the results of the disease rather than the disease itself?" I am sure Dr. Hernaman-Johnson did not intend this sentence to be as disparaging as it sounds.

Fortunate is the patient with ankylosing spondylitis who comes under the care of an orthopaedic surgeon at an early stage in his disease. The latter clearly enjoys an advantage over certain of his colleagues in knowing that he is unable to cure the patient. He also knows that the end-result of the disease is a "poker back," and that there is a grave risk of costo-vertebral ankylosis and a consequent lowering of resistance to respiratory infection. He knows too that in most cases radiotherapy is effective in relieving the patient's pain. He therefore takes steps to ensure that the spine ankyloses straight and to maintain the respiratory excursion of the chest by appropriate exercises until the disease has "burnt out." He will also, in all humility, refer the patient to the radiotherapist. By such means the tragedy of the patient with a "question-mark" spine, unable to see more than five yards in front of his feet, can be avoided.

Of patients treated in the orthopaedic department of the Sheffield Royal Infirmary, I quote two examples. One served in the London Fire Service throughout the "blitz," being treated without avail by a variety of medical methods. Happily his spine flexion was controlled in time by a brace, and, now ankylosed, he works actively in an important position. The other is still serving as first mate on an oil-tanker. Although his spine is rigid from sacrum to skull, he stands straight.—I am, etc.,

Sheffield.

F. GODSALVE WARD.

Adoption of Children

SIR,—In a court case reported in the newspapers recently a childless couple were bound over for neglecting an adopted child aged 6½ years. The child, adopted at the age of 14 months through an adoption society, proved to be educationally subnormal. Medical examination of children for adoption should at least ensure that mentally subnormal children are not passed as fit for adoption.

At present the examination of such children may be carried out by any medical practitioner, who may or may not be familiar with the norms of mental development in children. I would like to make a plea that examination of children for adoption is only carried out by doctors who have a specialized knowledge of the developmental assessment of children. Only in such a way can the repetition of a disaster as described in the newspaper reports be avoided.—I am, etc.,

London, S.E.13.

G. G. JONES.

Dosage of Heroin

SIR,—Dr. J. H. Crawford and Dr. James Ross (April 30, p. 776) are right in emphasizing that in the two alarming cases reported by me (April 9, p. 619) the doses of heroin administered were excessive. The administrator had been led towards excess by three circumstances. (1) The opinion, which certainly has been current, that heroin is a safer and milder drug than morphine. (2) His possession of tubes of heroin tablets of 1/6 gr. (11 mg.) issued by a long-established and reliable firm of chemists. (3) His previous experience that this dose had produced little obvious effect. Dr. James Ross's shrewd reasoning that this experience may have related to patients with vigorous metabolism is correct—they were pregnant and parturient women.

I venture to suggest these conclusions. Patients differ considerably in their resistance to the depressing effects of heroin, chiefly according to their metabolic vigour. The margin of safety, never too wide for care, may become narrow enough for anxiety in a patient with lowered metabolism. A large dose of heroin in a much debilitated patient may cause dangerous symptoms. Heroin should not be administered to such a patient without special consideration, and only in reduced doses. Tablets and other unitary preparations of drugs should not be issued containing doses in excess of the official maximum.—I am, etc.,

Birmingham.

CRANSTON WALKER.

Approach to the Frontal Lobes

SIR,—The restatement of his views by Dr. P. Glees (April 30, p. 780) seems to leave us less ground for disagreement. However, I am not convinced he has established his main point, that abolition of transorbital lobotomy would accelerate our understanding of other lobotomy processes—or, as he puts it, that “any new blind approach will delay the understanding of the underlying mechanism of mental recovery after lobotomy.” No one suggests that the transorbital technique should be used in 100% of cases, and it is difficult to believe that its occasional employment will seriously retard the advance of knowledge. Electro-convulsive therapy is also a treatment where the rationale is not clear, but its empirical use did not stultify research nor delay the present refinements of technique. This is to my mind a more fair analogy than Dr. Glees’s comparison of transorbital lobotomy with a blind abdominal operation for the relief of constipation.

It seems better to me to give help where we can rather than withhold it on perfectionist grounds. There is a section of patients which one judges might benefit from psychosurgery and from nothing else, yet at the present level of medical services, and for a long time to come, they cannot be given the staffing and organization demanded by elaborate operative research. Since we have reasonable grounds for believing that the simple and relatively safe procedure of transorbital lobotomy might assist them and that at the worst it is unlikely to do harm, as a temporary expedient, pending the development of more definitive techniques, I see no very good argument against giving it at least a more extended clinical trial—I am, etc.,

Ilkley, Yorks.

MAX VALENTINE.

Shoulder-harness

SIR,—Fortunately it was the need for improvisation and not personal injury and discomfort, as in the case of Sir H. J. Manockjee Cursetjee (April 30, p. 779), which suggested to me an appliance for fractured clavicle or clavicles which would obviate the discomfort caused by the usual methods.

When such accidents have occurred during the last ten years I have invariably made use of two rubber “deck tennis” rings. An arm is inserted in each, and the shoulders are braced by a strap or webbing band connecting them across the shoulders. They are soft, pliable, and easily washed, and the comparative comfort is endorsed by a patient who had previously fractured one clavicle once and the other twice.—I am, etc.,

Cardiff.

J. P. H. DAVIES.

POINTS FROM LETTERS

Hereditary Cheiropompholyx

Dr. S. H. CURRY (Surbiton) writes: I have recently seen a case of hereditary cheiropompholyx which I feel must be very unusual. The case was a male child of 6 months, and on examination he showed a vesicular eruption of the right hand. Some of the vesicles were secondarily infected. I ensured that there was no fungus infection by microscopic examination. I treated the patient with a coal-tar ointment applied to the affected parts, and penicillin injections. The following day I saw the father of the child, and he complained of a similar eruption on the hands from time to time. He said it first occurred in hot weather and was diagnosed in India as cheiropompholyx. Again the base of the vesicles showed no evidence of fungus, and I was thoroughly satisfied that this was a case of cheiropompholyx. He responded well to the same treatment as his child, and both were discharged on the same day, after three weeks’ treatment.

Obituary

Sir FREDERICK MENZIES, K.B.E., M.D., F.R.C.P.

Former Medical Officer of Health and School Medical Officer, London County Council

Sir Frederick Menzies, formerly medical officer of health and school medical officer of the London County Council, died suddenly on May 14 at his home in London at the age of 73.

Frederick Norton Kay Menzies was born in 1875, the son of a civil engineer at Caernarvon, North Wales. He graduated M.B., Ch.B. at Edinburgh University in 1899, proceeding M.D. with distinction in 1903. He took the M.R.C.P.Ed. in the same year, and the fellowship four years later. He had postgraduate experience in the universities of Vienna, Berlin, and Paris, and held resident posts at the Royal Infirmary, Edinburgh; the Brompton Hospital; the Children’s Hospital, Great Ormond Street; and at the Western Fever Hospital, Fulham. For five years he was demonstrator and lecturer in the public health laboratory at University College, London. After taking his D.P.H. in 1905 Menzies became in 1907 deputy medical officer of health for the borough of Stoke Newington. He held also part-time appointments as examiner in public health and hygiene to the Board of Education, the City and Guilds Institute, and the Royal Sanitary Institute.

[Lafayette]

Menzies began his long service with the London County Council in 1909 as a part-time school medical officer. Two years later he was appointed a whole-time assistant medical officer on the Council’s staff. By 1914 he had become principal assistant medical officer, and in 1926 he succeeded his chief, the late Sir William Hamer, as medical officer of health and school medical officer. His main task in 1911 was to organize the first of the five areas—east and north-east London—into which the county was divided for the purpose of the school medical service. A year later he drew up the scheme for the diagnosis and treatment of tuberculosis, and during the war of 1914–18 the scheme for the provision of facilities for the diagnosis and treatment of venereal diseases. Menzies was also responsible in those early years for all the work in connexion with maternity and child welfare, infant life protection, and the midwifery service. Just before his appointment as chief medical officer there came a short period of broken service under the L.C.C. In 1924 Menzies resigned his position as a principal assistant medical officer and was appointed to the temporary post of consultant to the Council in connexion with its tuberculosis and venereal diseases schemes. During the ensuing 21 months he undertook a great deal of work on behalf of the Voluntary Hospitals Commission, the joint Council of the British Red Cross Society and the Order of St. John, and the United Services Fund. These three organizations at that time were either distributing or had recently distributed large grants of money, arising from war funds, to voluntary hospitals throughout England and Wales. His visits of inspection took him to all kinds of straits and convalescent homes in different parts of the country and was a valuable, though an unintended, preparation for the new duties that awaited him in London within the next few years. His return to the full-time work of the Council was without owing to representations which were made by prominent members of that body who realized that great hospital developments were impending. They felt that the enlarged responsibility which would fall to the Council called for an officer in the public health department who had had experience of large-scale hospital administration and organization. Mr. Neville Chamberlain, then Minister of

Health, had brought forward just at this time his provisional proposals for the reform of the Poor Law. These proposals were eventually embodied in the Local Government Act, 1929. Menzies agreed therefore to rejoin the Council's service at the end of 1925, when Sir William Hamer retired.

Menzies undertook then the preparatory work needed in view of the approaching legislation. Under the Act of 1929 the whole of the general and special hospitals and medical services of the metropolitan boards of guardians and the Metropolitan Asylums Board were taken over by the L.C.C. A new hospital authority came into existence overnight on April 1, 1930, and with such smoothness was the transfer accomplished that hardly any of the 20,000 staff or the 42,000 patients realized that anything unusual had occurred. About 80 hospitals and other institutions came under Menzies's direction and control. But that was only the beginning, and as the hospital service went on developing, its efficiency increasing year by year, it became the largest service under unified control in the world.

The work of building up an efficient department both for the public health and for the hospital services of London continued steadily. An important step forward was taken with the establishment of the British Postgraduate School and its attachment to the Hammersmith L.C.C. Hospital, and in this development Menzies played his part. Then in 1939 the war brought about a disruption which Menzies felt deeply. Perhaps he took a too sombre view when he saw what had almost been his life-work frustrated. In a private letter at the time he spoke of the service as being "completely smashed up as a unit organization," and of "a tragic end to a long career in the service of London." He had suffered under a handicap of physical infirmity for some years, and on several occasions he had described himself as a very tired man and had expressed his desire to be released. He therefore, after nearly fourteen years at the head of the L.C.C. public health department, tendered his resignation, which took effect on his sixty-fourth birthday, Nov. 2, 1939. The Emergency Committee of the Council, which owing to the war was then in charge of all the Council's business, in accepting the resignation, reported that "it was in no small degree due to the preliminary work and foresight of Sir Frederick Menzies that the transfer of the hospitals was effected so smoothly." The report added: "His retirement will deprive the Council of the services of an officer in whom it has justifiably placed the highest confidence. The strength and graciousness of his character and personality have won the respect and esteem of the members of the Council and of the members of his staff both at the central office and at the hospitals." The Council added five years to his period of pensionable service as a mark of its special regard, and when he bade it farewell high tribute was paid to him by the leader of the Council, Mr. Herbert Morrison, who declared him to have been one of the greatest chief officers the L.C.C. ever had.

Among the many offices which Sir Frederick Menzies held at one time or another outside his Council work were the chairmanship of the Central Council for Maternity and Child Welfare, membership of the Council of the National Association for the Prevention of Tuberculosis, and chairmanship of the committee of management of its Burrow Hill Colony. He was a member of the board of governors of the London Hospital and of Queen Mary's Hospital, Roehampton. He represented Great Britain at the international congresses of Red Cross Societies. The Government committees upon which he served included the Trevelthick Committee of inquiry into venereal diseases, the Ministry of Health Committee on the training and employment of midwives, the Home Office Advisory Committee on the scientific investigation of crime, and the Interdepartmental Committee on nursing services. He was a member of the Voluntary Hospitals Commission from 1923 to 1928, and a member of the Committee of Reference of the Royal Colleges dealing with the recruitment and allocation of consultant staff for war service in 1939. For years he served the Central Midwives Board and the General Nursing Council. Many honours and decorations came his way. He was knighted in 1932, and in 1937 was one of the several persons to the King appointed from members of the Council engaged in public health work. He became a Knight of Grace of the Order of St. John of Jerusalem in 1934. In 1932 he was elected F.R.C.P. under the by-law which admits to the Fellowship a certain number of persons, not members

of the College, who have distinguished themselves in any branch of the science or practice of medicine. In 1941 the College awarded him its Bisset-Hawkins gold medal for his work in the public health field. He was a Fellow of the Royal Society of Edinburgh, and in 1934 he received from the Royal College of Physicians of Edinburgh the Cullen Prize awarded every four years "for the greatest benefit done to practical medicine." In the previous year he received the honorary LL.D. of his old university on the occasion of the 350th anniversary of its foundation, when only one nomination was allotted to each of the various faculties, and he was chosen as representative of medicine, the Public Orator describing him as "one of the foremost exponents of preventive medicine in this country."

In his social as well as in his public life Sir Frederick Menzies was a forceful and decisive but very likeable personality. At his country home in Norfolk he revealed himself as something other than the dominant high official of County Hall; here he was a gentleman farmer, finding his recreations in gardening, farming, estate management, and country sport.

Sir Allen Daley writes: Sir Frederick Menzies was probably the greatest hospital administrator which this country, or indeed any other, has ever known. He set himself the task of welding the hospitals of the Metropolitan Asylums Board and those of the 25 Metropolitan boards of guardians into a comprehensive hospital service for London which would be the finest as well as the largest under local government administration in the world. Many of the hospitals were almost obsolete, and the standards of staffing varied greatly; the economic crisis of 1931 added to his difficulties. Nevertheless, by the time that he retired in 1939 he had made substantial progress towards the implementation of his plans, and had it not been for the war his ambitions would by now have been fully attained. He had had long experience in the best voluntary hospitals and remained actively associated with many of them. He was active in the affairs of the King Edward Fund and the Nuffield Provincial Hospitals Trust. This close association with the voluntary hospital world helped substantially his organization of the municipal hospitals and his efforts to reach a working arrangement with them. Menzies had no patience with recent changes in the hospital world, and enlivened discussion by many caustic comments upon them. He had enormous influence and prestige at County Hall. He was not dependent financially on his official position, and this enabled him to take a strong line whenever he felt that this was necessary. He was a genial but exacting chief. He left a great deal to his staff, but always supported them when they ran into difficulty. His knowledge of when to press forward with a scheme and when to defer it until a more propitious moment was uncanny. At heart Menzies was a countryman. He was an expert in estate management, and nothing gave him greater pleasure than a day in the open air with a gun and a dog. This form of recreation, however, had been curtailed since 1934, when he had a serious illness as a result of which he could not walk more than a quarter of a mile without resting. Since he sold his Norfolk estate he had lived in London except for the war years, when he returned to his native Caernarvonshire. For the past few years he had lived quietly in Kensington. In March he went to Port Said to see there the British Hospital, of the committee of which he was chairman. He developed pneumonia on the way back, and never completely regained his strength. His former colleagues mourn the loss of a great-hearted friend and a truly great man. He left a mark on the public health and hospital services of London which can never be effaced. Our deepest sympathy goes to his widow and to his son and daughter. His elder son, a regular soldier, was killed soon after the landing in Normandy in 1944.

W. N. WEST-WATSON, M.D.

Dr. William Norman West-Watson died at his home in Bradford on March 20. He was born at Birkenhead, and graduated M.B., Ch.B. at Glasgow University in 1903, proceeding M.D. in 1908. He was house-surgeon to Sir Hector Cameron, and later R.M.O. to the Jaffray Hospital, Birmingham. As a medical student he served in the South African War with a Scottish hospital unit, and was awarded the Queen's Medal with clasps. Before starting in general practice he was ship surgeon

to the Union Castle Line in 1908. On the outbreak of war West-Watson joined the R.A.M.C. and went to France in 1915. In this year he was appointed honorary assistant physician to the Bradford Royal Infirmary, becoming later physician and consultant. He joined the St. John Ambulance Brigade as corps surgeon, and was later assistant commissioner for the Midland Area (West Riding). He was made a commander of the Order of St. John of Jerusalem in 1946.

West-Watson will be best remembered for his work in connexion with the British Medical Association. He was a tower of strength to the Bradford Division, of which he was secretary from 1920 to 1932. He kept alive locally interest in the work of the Association. Many will recall the annual meeting held in Bradford in 1924, which owed much of its success to West-Watson's administrative ability and genius for organization. He was honoured the following year at Bath by being made vice-president of the Section of Medicine. A member of several central committees from 1921 onwards, and a member of Council from 1930 to 1943, he attended fourteen representative meetings between 1921 and 1938. He was chairman of the Bradford Division in 1933-4, and president of the Yorkshire Branch at the time of his death. At the meeting of Council last week Dr. Dain paid tribute to the work West-Watson had done for the Association, locally and centrally, for over twenty years.

When his full and active life ended, West-Watson was deputy-chairman of the Bradford Executive Council. He never spared himself, and even his holidays were few and short, and mostly devoted to golf. He played a good game, and up to recently had a handicap of ten. No record of his life would be complete without mention of his work for St. Luke's Church, Bradford. He was a regular attender, a warden, and gave characteristically devoted service. West-Watson suffered a cerebral haemorrhage in January last, made a study of his disability, and won through to attend meetings of the Executive Council and of the Division. Only a fortnight before his death he spoke at one meeting with his customary force and lucidity. Truly he died in harness. West-Watson never shirked responsibility, and when in the process of time he handed over his duties to others he continued to give freely of his ripe experience and wisdom. He owed much to his wife, who was always a gracious hostess on the many occasions when they dispensed hospitality. He is survived by her, three sons, and a daughter. All three sons served in the recent war.—G. P.

OWEN W. RICHARDS, C.M.G., D.S.O., D.M., M.Ch., F.R.C.S.

Mr. Owen William Richards, one of the distinguished surgeons of the 1914-18 war and later director of the Egyptian Government School of Medicine in Cairo, died at his home in Bideford on April 18 after a long and distressing illness. Owen Richards was the son of the Rev. H. W. P. Richards, Prebendary of St. Paul's. He was born at Isleworth vicarage on Sept. 30, 1873, and there he passed his early boyhood until he went to Eton as a King's Scholar. At New College, Oxford, he obtained first-class honours in physiology and became Wykeham Prize Fellow. He was then a student of Guy's Hospital, where he graduated in 1902, proceeding M.D. in 1905 and taking the F.R.C.S. in the same year. His studies were interrupted for a time by the South African War, when he served as a dresser and gained the Queen's Medal with three clasps. In 1905 Richards was appointed professor of clinical surgery at the School of Medicine in Cairo, and there he was responsible for some outstanding work. He was accustomed to ride out to the military hospital of the Egyptian Army at Abbassia, and he employed his leisure hours in practising operations on the intestines of a cow in order to perfect his technique. He did yeoman service in Cairo for the next nine years, and then on the outbreak of war in 1914 he retired from the Egyptian Service and took a commission in the R.A.M.C. He was posted to Versailles as a subaltern, and there he was found by Sir Arthur Sloggett and promoted to captain. His surgical skill soon became apparent, and by 1917 Richards was a colonel and finally a consultant surgeon and a member of the advisory council of the D.G.M.S. in France. He won the D.S.O., was appointed C.M.G., and was three times mentioned in despatches. He did splendid work at No. 6 C.C.S. at Merville and also in Béthune and Arras. He told Sir Cuthbert

Wallace and Sir Anthony Bowlby that if only he were given some extra equipment and placed nearer the front he thought he might do good work on abdominal cases close to the line without giving them the trying journey back to a clearing station before operation. His request was granted, though he was told, of course, that no sisters could be risked so far in advance; but the extra equipment and some additional orderlies made the arrangement he suggested possible, and in these circumstances some of his best work was done. After the war Richards returned to Egypt as director of the medical school and hospital at Kasr-el-Aini, being decorated later with the Order of the Nile (Second Class) for his services to medical education. He left the service of the Egyptian Government in 1924 under the arrangements made when Egypt became independent. In 1927 he settled at Downes, near Bideford, where he could indulge not only in his favourite sport of yachting but in the art of forestry. He planted many trees and supervised their growth; so much so that a forestry inspector once said that among small estates Downes was "one of the show places so far as forestry was concerned." The sympathy of many friends and colleagues will be extended to Mrs. Richards and her daughter.—S. L. C.

The Services

INDIAN MEDICAL SERVICE DINNER

The annual dinner of the Indian Medical Service will be held at the Connaught Rooms, Great Queen Street, Kingsway, London, W.C., on Wednesday, June 15, at 7 p.m. for 7.30 p.m., when the chair will be taken by Major-General Sir Gordon Covell. The cost of a ticket to subscribing members of the dinner club is 16s. 6d. and to others £2 2s. These charges cover drinks before and during the dinner, cigarettes, and gratuities to waiters. If possible full evening dress, with decorations, should be worn, the alternative being dinner-jacket, with which miniatures may be worn, or Service dress. Applications, with remittance, should be sent to Mr. A. W. Brown, of Grindlays Bank, Ltd., 54, Parliament Street, London, S.W.1, as early as possible.

Medical Notes in Parliament

Special Rations for Invalids

Answering Mr. DRIBERG on May 11, Dr. SUMMERSKILL announced that the Food Rationing (Special Diets) Advisory Committee had reviewed the present meat ration in relation to the needs of invalids and had recommended that no extra meat rations additional to those already allowed need be granted for diabetics or for cases of spontaneous hypoglycaemia. They were satisfied that the protein available in the present allowances of meat and cheese was quite adequate to construct any kind of diabetic diet. The Committee had also recommended that one further extra ration of meat should be allowed in cases of nephritis with gross oedema and gross albuminuria, for both types of hepatitis, and in cases of steatorrhoea.

Eyes and Ears.—It is estimated that up to March 31 about 5,620,000 sight tests had been made under the National Health Act. It is not known how many of these were examinations for the first time. About 19,000 patients in England and Wales have been supplied with Medresco hearing-aids since July 5, 1948. The number needing such aids is not known, but is not likely to be less than 150,000.

Leprosy.—Replying to Mr. HUBBARD on May 13 Mr. BEVAN said he was considering making leprosy notifiable. It was not notifiable at present, and reliable information about the number of cases was not available. There was one leper hospital in England, run by a voluntary body, which could accommodate 13 cases and had 12 there now. Arrangements were being made to supplement this by another provided as part of the National Health Service.

The two Sides of the Ancillary Staffs Council of the Whitley Councils for the Health Services have agreed that domestic staffs directly engaged in the care of smallpox and typhus patients, and who therefore have to be isolated and to undergo other inconveniences which the work involves, shall receive a 50% increase in wages while so engaged.

No. 17

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 30.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county). (c) Scotland (d) Eire. (e) Northern Ireland. Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are based on approximate figures only.

† Deaths from diphtheria and scarlet fever for England and Wales, London and Northern Ireland, and from smallpox for England and Wales, London (administrative county) and Northern Ireland.

‡ Deaths from pneumonia for England and Wales, London (administrative county) and Northern Ireland.

§ Deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county) and Northern Ireland.

|| Deaths from puerperal fever for England and Wales, Eire, and Northern Ireland.

EPIDEMIOLOGICAL NOTES

Typhoid Fever at Crowthorne

Further cases of typhoid fever associated with the Crowthorne, Berkshire, outbreak have been found at Ottershaw and Didcot. The total of confirmed cases is now 39, and two of these may prove to be secondary infections.

The foodstuff suspected of carrying the infection was on sale in the village on April 15, 16, and 19, and was all consumed in that period. The outbreak was self-limiting. The source is still under investigation.

A controlled trial of chloromycetin (chloramphenicol, Parke Davis) is in progress on patients in infectious diseases hospitals at Winchester and Mogden, Middlesex. The reports will not be published for some weeks, but there is every reason to believe that the encouraging results obtained by Woodward and his colleagues¹ will be confirmed by the present investigations. There were no undesirable side-effects from the use of the drug.

At Maidenhead 7 patients in hospital have received "therapeutic anti-typhoid (Vi+O) serum (Felix)," which appears to have influenced the third week of the disease.

Smallpox

The unvaccinated woman admitted to the Liskeard Smallpox Hospital on May 7 developed a semiconfluent rash and is severely ill. Three close contacts, all unvaccinated until five days after first contact, agreed to precautionary isolation in the Liskeard Smallpox Hospital. It was reported on May 16 that all three are sickening, and smallpox is expected to develop in two of them. In the third case vaccination after contact may have influenced the course and resulted in an infection without eruption.

A suspected case was admitted to the Ashey Smallpox Hospital, near Ryde, Isle of Wight, on the evening of May 14. This was on the third day of a severe illness, and the patient showed a confluent macular rash with the characteristic distribution of smallpox, except for a striking "butterfly" rash on the face. There was early vesiculation of some of the macules. On the fourth day there was extensive pustulation, and a diagnosis of acute disseminated lupus erythematosus was made. A negative complement-fixation test for variola-vaccinia was reported from the Central Public Health Laboratory on May 16. Confirmation of this negative result by egg culture is awaited.

Although several suspected cases have been seen elsewhere in England and Wales the only confirmed focus of infection is at Liskeard, Cornwall. The circumstances are in no way disturbing, but there is still a remote possibility of further cases of smallpox appearing, and special vigilance is necessary.

Discussion of Table

In England and Wales a decrease was reported in the notifications of measles 2,078, acute pneumonia 306, scarlet fever 168, and dysentery 14. There was an increase in the incidence of whooping-cough 359.

The largest falls in the notifications of measles were Yorkshire West Riding 236, Surrey 226, Southampton 171, Middlesex 160, London 158, Sussex 153, Kent 132, Derbyshire 121, and Oxfordshire 114. The only notable change in the incidence of scarlet fever was a fall of 47 in Lancashire.

The largest increases in the notifications of whooping-cough were Derbyshire 73, Kent 52, and Warwickshire 41.

An outbreak of dysentery affecting 8 persons was notified in Buckinghamshire, Aylesbury R.D. In Lancashire 10 cases were notified.

In Scotland large increases were reported in the notifications of measles 248 and whooping-cough 130, while decreases were recorded for acute primary pneumonia 107, scarlet fever 29, and diphtheria 13. Notifications of diphtheria were down to the record low level of 20; in Glasgow there were 14 fewer cases notified than in the preceding week. The increase in the incidence of dysentery was contributed by Glasgow, where the notifications rose from 11 to 23.

In Eire decreases in the notifications of measles 68 and scarlet fever 35 resulted from a decreased incidence in Dublin C.B.

In Northern Ireland an increase of 38 in the notifications of whooping-cough was the only large change in the trends of infectious diseases. This increase was confined to Belfast C.B. and Co. Antrim.

Quarterly Returns for Northern Ireland

Births during the December quarter were equivalent to the rate of 20.2 per 1,000, which was 0.3 below the rate for the preceding December quarter and 1.5 below the average for

Stimulant action in emergency

Anacardone (Injection of Nikethamide B.D.H.) should be at hand in the surgery and in the doctor's bag ready for immediate use.

Nikethamide B.D.H. exerts a rapid stimulatory effect on the respiratory and vasomotor centres thus raising the depth and rate of respiration and improving the blood supply to the heart in acute collapse.

Anacardone is available in ampoules as Injection of Nikethamide B.P. and as a 25 per cent. solution, flavoured, for oral administration.

Introducing

NEW FORMULA

'Roche' B-Complex for oral and parenteral use

'Becosym' presents five important factors of the Vitamin B-Complex in two forms: Tablets and Twin-Ampoules.

EACH TABLET CONTAINS:	B-COMPLEX FACTORS	TWIN-AMPOULES CONTAIN:
5 mg.	vitamin B ₁ (aneurine, thiamin)	10 mg.
2 mg.	vitamin B ₂ (riboflavine)	4 mg.
20 mg.	nicotinamide (P.P. factor)	40 mg.
2 mg.	vitamin B ₆ (pyridoxine)	4 mg.
3 mg.	pantothenic acid	6 mg.

'BECOSYM'

Tablets are sugar-coated and issued in bottles of 25, 100 and 500. 'Becosym' for injection (intramuscular or intravenous) is stable and well-tolerated and is issued in boxes of 6 and 50 twin-ampoules.

ROCHE PRODUCTS LIMITED

HEPASTAB FORTE

HEPASTAB FORTE is a highly concentrated extract of liver which has been prepared in our Nottingham laboratories as the result of research conducted by our own chemists in co-operation with clinicians in this country and abroad. It contains all the known anti-anæmic factors of liver, is highly refined, painless on

injection, and highly concentrated. Each 1 c.c. of Hepastab Forte is obtained from 100 G. of liver and is therapeutically equivalent to 4,000-5,000 G. of fresh liver by mouth.

Ampoules of 1 c.c.: single ampoules, boxes of 3, 6 and 12 ampoules. Rubber-capped vials of 10 c.c.

Literature and further information gladly sent on request to Medical Department.
BOOTS PURE DRUG COMPANY LIMITED, NOTTINGHAM, ENGLAND.

B.1.

CESSANTE CAUSA, CESSAT EFFECTUS (COKE)

*By neutralizing the cause
you neutralize the effect.*

Neutralization of the excess acid in the stomach without impairment of the normal digestive processes is the key to the satisfactory treatment of hyperacidity and peptic ulcer.

'ALUDROX,' a suspension of 5.6% colloidal aluminium hydroxide in gel form, rapidly controls this free acid without interfering with combined acid. A peptic ulcer quickly heals and pain is promptly relieved. The aluminium hydroxide is excreted later unchanged, thus avoiding all risk of alkalosis.

terms of TONIC VALUE

First and foremost, Minadex is a *children's* tonic. It takes the short cut to a child's favour with its delightful orange tang . . . ensures 'patient co-operation' right from the start. Yet Minadex is a tonic in the truest sense of the word. It contains the protective vitamins A and D not just in nominal amounts but in therapeutic doses; it provides iron to aid formation of healthy blood; and, in addition, the glycerophosphates of calcium, potassium, sodium and manganese, together with copper sulphate. N.H.S. prescriptions are revealing more and more preference for Minadex . . . and are showing that doctors realise how the same qualities that commend Minadex for the youthful patient are just as valuable to grown-ups!

GLAXO

Syrup MINADEX

in 6 oz. and
12 oz. bottles

Each fluid ounce contains: Vitamin A 18,000 i.u. Vitamin D 3,000 i.u.
Iron and ammonium citrate 13½ grains. Calcium glycerophosphate 2 grains.
potassium, sodium, and manganese glycerophosphates; copper sulphate.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX BY Ron 3434

the fourth quarters of the five years 1943-7. Infant mortality was 44 per 1,000 registered births and was 18 below the average of the fourth quarters of the five preceding years. Maternal mortality was 1.6 per 1,000 births and was 0.8 below the five years' average. The general death rate at 10.9 per 1,000 was 1.2 below the five years' average. The death rate from tuberculosis, 61 per 100,000, was the lowest ever recorded, except for the December quarter of 1947, and was 12 below the five years' average.

For the whole of 1948 the birth rate was 21.9 per 1,000, a decrease of 1.4 on 1947 and 1.2 below the average of the five preceding years. The death rate, 11.3 per 1,000, was the lowest ever recorded in Northern Ireland. The infant mortality, 46 per 1,000 live births, was also the lowest ever recorded, being 7 below the rate for 1947, the previous lowest level.

Week Ending May 7

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 898, whooping-cough 3,053, diphtheria 87, measles 9,217, acute pneumonia 494, cerebrospinal fever 21, acute poliomyelitis 13, dysentery 59, paratyphoid 3, and typhoid 37.

Medical News

The Centenary of the Brompton Hospital

It is hoped to hold a dinner in November of this year to celebrate the centenary of the Brompton Hospital. All those who have been on the medical staff or residents of the hospital who would like to be present at the dinner are asked to send their names and addresses to the House Governor, who will in due course give them further details of this notable occasion.

Honorary Fellow

Professor Grey Turner has been elected an Honorary Fellow of the American Surgical Association.

Irish Medical Graduates

A general meeting of the Irish Medical Schools and Graduates Association was held in the South Kensington Hotel, London, on April 21. This association of Irish medical men was inaugurated in 1878 and is the oldest Irish medical society in England. It has in its gift the presentation of the Arnott Memorial Medal, and among its recipients have been many famous Irishmen. An Arnott Memorial Medal was presented by Colonel George Moore to the president of the association, Mr. Johnston Abraham. It was unanimously agreed at the meeting that the association, which has held no functions since 1938, should resume its activities. Those qualified to become members and wishing to join are asked to write to the secretaries, Dr. J. Bodkin Adams, 6, Seaside Road, Eastbourne, or Mr. W. McKim H. McCullagh, 149, Harley Street, London, W.1.

Committee on Radioactive Substances

Sir Henry Dale, O.M., F.R.S., has been appointed chairman of the Radioactive Substances Advisory Committee, which will advise on protective measures against radioactivity. The committee has been appointed by four Ministers—the Minister of Health, the Secretary of State for Scotland, the Minister of Supply, and the Minister of Health and Local Government for Northern Ireland—to advise the Ministers on measures to safeguard workpeople and the public generally against the danger of exposure to radiation from radioactive substances and certain irradiating apparatus. The appointments made under Section 6 of the Radioactive Substances Act, 1948, are for three years. The other members are: Mr. J. P. Baxter, Ph.D.; Mr. W. Binks, M.Sc.; Sir Ernest Rock Carling; Mr. D. G. Catchside, M.A.; Lord Cherwell, F.R.S.; Sir John Cockcroft, F.R.S.; Professor N. Feather, F.R.S.; Mr. L. H. Gray, Ph.D.; Captain Mark Hewitson, M.P.; Dr. J. F. Loutit; Professor W. V. Mayneord; Professor R. McWhirter; Dr. E. R. A. Mereweather; Dr. Ralston Paterson; Mr. H. S. Souttar; Sir George Thomson, F.R.S.; Professor B. W. Windeyer.

Honours Conferred by the Society of Apothecaries

Two eminent scientists were honoured by the Society of Apothecaries in London on May 11 in the presence of a distinguished company, including the French Ambassador. In presenting the Gold Medal in Therapeutics to Professor Jacques Tréfouël, Director of the Institut Pasteur, the Master of the Apothecaries, Professor E. C. Dodds, referred to Professor Tréfouël's clarification of the fundamental rules of chemotherapy. His work on the sulphanilamide preparations, in which his wife collaborated, led to the development of the sulphonamide group of drugs, and was the keystone on which all later research on these drugs was built. Professor Tréfouël's reply in English was brief, modest, and to the point. The Honorary Freedom of the Society was then conferred on Sir Charles Harington,

Director of the National Institute for Medical Research. The Master of the Society said that all the work on thyrotoxicosis being done to-day would have been impossible without an understanding of the way in which the thyroid gland works; that understanding was owed to Sir Charles Harington, who first succeeded in characterizing thyroxine and later in synthesizing it. His chemical studies on immunity were also of the greatest importance in medical research. Sir Charles Harington expressed his gratitude for the honour conferred on him. He pointed out that the position of biochemistry as an independent branch had not been achieved without great efforts. Now the work of biochemists was recognized and appreciated, and they could look back with pride along their line of descent from the apothecary.

Chelsea Clinical Society

The annual dinner of the Chelsea Clinical Society was held on May 10, the president, Mr. Nils Eckhoff, being in the chair. In proposing the health of the society, Mr. H. G. Strauss, K.C., M.P., said that the law had every reason to be grateful to the expert witness. Continuing his crusade against the misuse of English, he said he understood that the word "hospitalized" did not mean being converted into a hospital but being sent to one. He gave the society this definition of an intellectual—a man educated beyond his intelligence. In reply, the president referred to the activities of the society during the past year, mentioning the discussions that had taken place on empiricism, films, radioactive isotopes, Graves's disease, and prefrontal leucotomy. He paid tribute to the work of the secretaries of the society for making it a flourishing concern. The health of the guests was proposed in the wittiest speech of the evening by Mr. Frank Cook, and responded to by Air Marshal Sir Richard Peck. The evening concluded with the inauguration of the president for the coming year, Dr. Maurice Bewley.

Hospitals May Close

As a result of the 10% cut in hospital expenditure ordered by the Minister of Health, a number of hospital boards and management committees have announced that they can economize only by closing hospitals or beds. According to Press reports the Manchester Regional Hospital Board has announced that the Stretford Memorial Hospital and the Eccles and Patricroft Hospital may have to close. Others in that region that may be closed are the Victoria Hospital, Accrington; Coplow View, Clitheroe; Parkside, Lancaster; and St. Anne's-on-Sea Memorial Hospital. The Arundel Hospital, in the Worthing Group, may have to close, and the Salisbury Group Hospital Management Committee thinks that it may have to close a small hospital, and that it would be unable to open a new extension ward in a tuberculosis sanatorium for which staff is available. The Windsor Group Management Committee considers that it must close 158 beds if it is to economize further. The North-West Regional Hospital Board is reported to be asking the Minister how it can make the economies required without closing 500 beds.

Streptomycin Royalties for Rutgers University

Dr. S. Waksman, who discovered streptomycin, has presented the money which patent rights on the drug bring him to Rutgers University, New Brunswick. The university will use the money to establish an Institute of Microbiology, with Dr. Waksman as its first director. A new million-dollar building will be erected and the balance will be used to cover operating expenses. Dr. Waksman has handed his patents to the Rutgers Research and Endowment Foundation, on the understanding that any further income will be used to promote research, particularly in microbiology. Royalties on the drug, computed at 24% of the sale price, totalled between £175,000 and £200,000 last year, according to the B.U.P. report which gives these figures. Dr. Waksman, who was born in Russia, came to the United States in 1910 and has been on the staff of Rutgers University for twenty-five years.

Postgraduate Medical Education

Sir John Anderson is the chairman of a Joint Board which has been set up by the three Royal Colleges and the British Postgraduate Federation. The Joint Board is "to consider the existing provisions for the postgraduate education and training of specialists, and invite the attention of medical schools and institutes, hospital authorities, and other bodies providing postgraduate medical education, to such modifications as may from time to time appear desirable." The members of the Joint Board are: Lord Moran and Dr. H. E. A. Boldero; Lord Webb-Johnson and Mr. Julian Taylor; Sir William Gilliatt and Mr. G. F. Gibberd; and Professor Sir Francis Fraser and Mr. J. B. Hunter.

Attending Congress in Turkey

Sir Howard Florey, Professor of Pathology in the University of Oxford, left Oxford on May 10 for Istanbul to attend the Fifth International Congress of Comparative Pathology as a delegate of the Royal Society. He will visit Greece between May 21 and 28 under the auspices of the British Council to lecture to the University of Athens medical faculty on "Antibiotics in the Treatment of Tuberculosis" and "Recent Progress in the Investigation of Antibiotics."

Association for the Paralyzed

The British Council for Rehabilitation has recently set up the National Association for the Paralyzed, which will be concerned with the care, treatment, and rehabilitation of the paralyzed. The National Association would be helped in compiling a register if all who are in touch with paralyzed persons would ask them to send their names and addresses, with a statement of the type of paralysis from which they suffer, to the Registrar, the National Association for the Paralyzed, British Council for Rehabilitation, 32, Shaftesbury Avenue, London, W.1.

Wills

Professor Arthur Robinson, formerly professor of anatomy at Edinburgh University, at King's College, London, and at Birmingham University, left £23,453. Dr. Henry Morrison, of North Walsham, Norfolk, left £26,409; Dr. David Carlyle Sutton, late of Chester, £46,430; and Dr. Richard Burges, of Stoke Bishop, Bristol, £20,005.

COMING EVENTS

Medical Art Society

The annual exhibition of the Medical Art Society will be held at Walker's Galleries, 118, New Bond Street, London, W., from Friday, May 20, to Thursday, June 2. All inquiries should be addressed to the honorary secretary of the society, Dr. Henry Wilson, 142, Harley Street, London, W.1.

Charities Ball

A Charities Ball organized by the Metropolitan Counties Branch of the B.M.A. will be held at B.M.A. House, Tavistock Square, London, W.C.1, on Thursday, May 26, at 8 p.m. for 8.30 p.m. The proceeds will be devoted to medical charities in urgent need of support. Patrons include the President of the Association and the Presidents of the three Royal Colleges. There will also be a cabaret and facilities for bridge. The cost of tickets including a buffet supper is two guineas each. Applications should be sent to the Secretary, the Charities Ball Committee, Metropolitan Counties Branch, B.M.A. House. Contributions to charities from those unable to attend the ball would also be most welcome and should be sent to the same address.

SOCIETIES AND LECTURES

Monday

LONDON: UNIVERSITY COLLEGE.—At Physiology Theatre, Gower Street, W.C., May 23, 4.45 p.m., "Selective Toxicity with Special Reference to Chemotherapy," by Professor Adrien Albert.

Tuesday

EUGENICS SOCIETY.—At Royal Society, Burlington House, Piccadilly, London, W., May 24, 5.30 p.m., "Some Biological Considerations in Social Evolution," by Professor H. J. Fleure, F.R.S.

INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—May 24, 5 p.m., "Choice of Vehicles for Topical Application," by Dr. W. H. Goldsmith.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., May 24, (1) 11 a.m., "Prognosis of Syphilis (Treated and Untreated)," by Dr. V. E. Lloyd; (2) 5 p.m., "Infections of the Urinary Tract other than Tuberculosis, I," by Mr. A. Clifford Morson.

LONDON UNIVERSITY.—At London School of Economics and Political Science, Houghton Street, Aldwych, W.C., May 24, 5 p.m., "The National Health Service," by Sir James S. Ross.

LONDON UNIVERSITY.—At Westminster Medical School, Horseferry Road, S.W., May 24, 5.30 p.m., "Applications of Polarography to Medicine," by Dr. Rudolph Brdicka (Prague).

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School, Paddington, W.—May 24, 5 p.m., "Bacterial Nutrition," by Dr. M. R. Pollock.

Wednesday

GLASGOW UNIVERSITY DEPARTMENT OF OPHTHALMOLOGY.—May 25, 8 p.m., "Bleeding and Clotting within the Eye," by Dr. W. O. G. Taylor.

HARVEIAN SOCIETY OF LONDON.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., May 25, 5 p.m., "The War Collection," Harveian Lecture by Sir Gordon Gordon-Taylor.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., May 25, (1) 11 a.m., "Toxic Manifestations due to Treatment of Syphilis," by Dr. W. N. Mascall; (2) 5 p.m., "Calculus Disease of the Kidney and Ureter, II," by Mr. H. P. Winsbury-White.

ROYAL MICROSCOPICAL SOCIETY.—At B.M.A. House, Tavistock Square, London, W.C., May 25, 6 p.m., Combined meeting of Biological and Industrial Sections. "The Theory and Practice of Section Cutting," by Mr. G. W. Moore.

SOCIETY OF CHEMICAL INDUSTRY'S LEAD GROUP.—At Anthony Green, Gloucester Place, Brighton, May 27, 10 a.m., joint meeting with the Royal Sanitary Institute. General subject of discussion: "The Care and Preservation of Fish as Food." Opening Address by Dr. E. B. Huxley, followed by four papers: (1) "General Introduction to the Biological Problems of the Fish Industry," by G. A. Reay, M.A., Ph.D., F.R.C.; (2) "Some Physiological Aspects of Handling, Processing, and Distribution of Fish," by J. M. Shewan, Ph.D., A.R.C.; (3) "Trends and Developments in Fish Technology," by C. I. Cutting, Ph.D.; (4) "Food Hygiene as Applied in the Marketing and Distribution of Fish," by Dr. J. A. Keir. Time allowed for discussion.

Thursday

BIRMINGHAM UNIVERSITY.—At Anthony Theatre Medical School, Birmingham, May 26, 4 p.m., "The Problem of Street Infection: Cause of Ulcer in the Leg," Ingleby Lecture by Mr. Charles D. Reid.

EDINBURGH UNIVERSITY.—At Anthony Theatre, University New Buildings, Teviot Place, Edinburgh, May 26, 5 p.m., "The Outlook for the Diabetic," Huxley Memorial Lecture by Dr. J. Holliday Crozer.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., May 26, (1) 11 a.m., "Toxic Manifestations due to Treatment of Syphilis," by Dr. W. N. Mascall; (2) 5 p.m., "Infections of the Urinary Tract other than Tuberculosis, II," by Mr. A. Clifford Morson.

LONDON UNIVERSITY.—At Westminster Medical School, Horseferry Road, S.W., May 26, 5.30 p.m., "Applications of Polarography to Medicine," by Dr. Rudolph Brdicka (Prague).

MEDICO-LEGAL SOCIETY.—At 26, Portland Place, London, W., May 26, 8.15 p.m., "The Medical Services in Race-track Concentration Camps," by Major A. K. Mart.

SOCIETY OF PUBLIC ANALYSTS: BIOLOGICAL METHODS GROUP.—At No. 3 Room Gas Industry House, 1, Grosvenor Place, London, S.W., May 26, 6.30 p.m., "Use of a Rotating Drum in Assessing the Activities of Paralytic, Convulsant, and Anesthetic Drugs," by Messrs. H. O. J. Collier, E. C. Heller, and R. A. Hill; "The Microbiology of Decay of Growth Factors after Paper Chromatography," by Mr. J. S. Harrison; "A Method for Determining the Potency of Heparin," by Mr. R. F. Long.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—May 26, 4.30 p.m., "Psychiatry," lecture-demonstration by Dr. D. Curran.

Friday

EDINBURGH UNIVERSITY.—At Physiology Lecture Theatre, University New Buildings, Teviot Place, Edinburgh, May 27, 5 p.m., "Greek and Roman Medicine," by Dr. Douglas Guthrie.

KENT AND CANTERBURY HOSPITAL, Canterbury.—May 27, 5 p.m. to 7 p.m., clinical meeting.

APPOINTMENTS

BROWN, JOHN KERR, M.B., Ch.B., D.P.H., Medical Officer of Health, Metropolitan Borough of Greenwich.

CATTINER, J. F., M.B., Ch.B., D.P.H., Medical Officer of Health, Borough of Batley, and Divisional Medical Officer, West Riding County Council.

LEAKEY, BARBARA M., M.B., B.S., Assistant County Medical Officer, West Riding of Yorkshire.

RILEY, JAMES F., M.D., F.R.C.S. Ed., D.M.R.T., Assistant Radiotherapist, Royal Infirmary, Dundee.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Collins.—On May 2, 1949, at Moorlands Nursing Home, Kenilworth, to Violet, wife of Dr. W. Collins, a son.

Evans.—On May 11, 1949, at Nuffield House, Guy's Hospital, London, S.E., to Winifred (née Groom) wife of Dr. M. L. Hudson Evans, Lewisham, a sister for Timothy-Sara.

Hopkinson.—On April 22, 1949, at Preston Infirmary, to Sylvia, wife of Dr. J. J. Hopkinson, a daughter—Susan.

DEATHS

Dale.—On April 28, 1949, at "Arley," Selbourne Road West, Worcester, Arthur James Dale, M.D., aged 79.

Forrest.—On April 30, 1949, James Forrest, M.B., Ch.B., of 1, Duke Street, London, W., aged 72.

Hett.—On May 3, 1949, in London, Geoffrey Seccombe Hett, F.R.C.S., aged 70.

Hume.—On May 2, 1949, at 27, Fitzroy Square, London, W., John Gordon Hume, M.R.C.S., L.R.C.P., aged 78.

Jones.—On April 30, 1949, at a nursing-home, Joseph Jones, M.D., of Howarth Cross, Leigh, Lanes.

Nelson.—On May 3, 1949, in London, Michael Louis Nelson, L.R.C.P.S. Ed., L.R.F.P.S. Glas., of Sydney, Australia, and late of Assouan, Egypt.

O'Dowd.—On April 27, 1949, at Jersey, C.I., Francis John O'Dowd, D.S.O., M.R.C.S., L.R.C.P., late I.M.S., aged 38.

Riddell.—On May 4, 1949, at Langbank, Bonness-on-Windermere, David Riddell, M.D., aged 71.

Snook.—On April 29, 1949, at Salisbury, Wilts, Samuel Penny Snook, M.R.C.S., L.R.C.P., of Weymouth, Dorset.

Strachan.—On Feb. 20, 1949, at Johannesburg, South Africa, Archibald Sutherland Strachan, M.D.

Whitwam.—On April 22, 1949, at Pargnton, Leonard Sykes Whitwam, M.B., Ch.B., Surgeon Commander R.N., retired, aged 74.

Wilson.—On April 26, 1949, at Gwynfryn, Denbigh, Robert Scott Wilson, L.R.C.P.S. Ed., L.R.F.P.S. Glas.

Wood.—On April 17, 1949, Charles Cruden Wood, M.B., Ch.B., of 15, Trevor Street, London, S.W.7.

Woodwright.—On May 2, 1949, at 13, Collingham Road, London, S.W., Charles Sharnan Woodwright, C.B.E., L.R.C.P.S. Ed., & L.M., Surgeon Rear-Admiral R.N., retired.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Penicillin Inhalations

Q.—Is inhalation of penicillin by means of an electric pneumostat recognized as part of the successful treatment of bronchiectasis? If so, can you tell me the strength of the penicillin solution employed, the period of daily treatment, and the average time required to produce improvement? What other diseases benefit from this method?

A.—Inhalations of penicillin with the help of various types of apparatus have been usefully employed in the treatment of many respiratory infections. In bronchiectasis they will diminish the quantity of sputum and produce general symptomatic improvement; these benefits are transient, and within a few days of stopping the inhalations the patient will have returned to his previous condition. Their main value is as a pre-operative measure to diminish the risks of lobectomy. Many different methods of inhalation have been used; in most about 30,000 units in a volume of some 10 ml. is vaporized and inhaled twice a day.

Apnoea on Tracheal Intubation

Q.—What is the cause of prolonged apnoea on passing an intratracheal tube orally? The anaesthetic sequence was cocaine, thiopentone, cyclopropane, and ether given by a closed-circuit machine. An attempt was made to establish respiration by forcing a little ether vapour into the lungs. What is the danger of the condition and how can it be prevented or treated?

A.—The passage of an endotracheal tube through the larynx is commonly followed by a period of apnoea. This is reflex in origin and, as might be expected, is usually encountered when intubation is performed under light anaesthesia. As a rule the apnoea is of short duration and spontaneous respiration soon starts. Should the apnoea persist or cyanosis develop, one or two gentle inflations of the lungs with oxygen will usually restore the patient's colour and be followed by spontaneous respiration. An attempt to force ether vapour into the lungs in light anaesthesia may result in generalized bronchoconstriction as well as a persistence of the apnoea. The occurrence of this reflex may be prevented by effective surface analgesia of the larynx or deeper general anaesthesia before intubation is attempted. Certain risks are attached to the passage of endotracheal tubes under light anaesthesia. In addition to the anoxia associated with the apnoea described above, cardiac arrhythmias are frequently seen, while sudden death has been reported as occurring in these circumstances.

Iridocyclitis

Q.—What is the treatment for recurrent attacks of iridocyclitis with conjunctival oedema? In one of my patients the condition starts in the right eye and slowly clears up with "albicid" drops, but before it is entirely cured the left eye becomes affected. "Benadryl" has been tried, also a mercury end atropine ointment. The condition now recurs every fortnight.

A.—There is no clear answer to this question. Iridocyclitis is an inflammatory affection, and, as with other inflammatory diseases of the eye and elsewhere in the body, little is known of the pathology. A parallel to iridocyclitis is rheumatoid arthritis. Both conditions are distressingly common, and in both a mass of hypothetical causes, mainly of an infective character, have been postulated. Evidence in support of these views is scanty, and therapeutic measures have proved disappointing. Treatment must therefore be symptomatic. Albucid drops are useless, as there is no ocular infection in these cases. Benadryl has likewise no rational application, as there is nothing to suggest that iridocyclitis is allergic in

character. Atropine must be the standby to prevent complications consequent on iris adhesions and the formation of exudate. Iridocyclitis is sometimes found in association with low-grade pulmonary tuberculosis, and also with rheumatoid arthritis and ankylosing spondylitis. The patient should be examined for the possible presence of these conditions. As empirical measures, heat in the form of short-wave diathermy in the acute phase, and x-ray treatment possibly in the quiescent phase, may have to be considered.

Inoculation in Pregnancy

Q.—A woman three months pregnant is joining her husband in Malta. Is vaccination or T.A.B. inoculation likely to have any adverse effect on mother or foetus?

A.—The theoretical risk is that in the event of a very severe reaction the hyperpyrexia might kill the foetus. In practice, however, no harm usually results, and the general view is that vaccination or T.A.B. inoculation is not contraindicated at any stage of pregnancy. J. A. Urner (*Amer. J. Obstet. Gynec.*, 1927, 13, 70) vaccinated 129 pregnant women, and there were no cases of abortion or premature labour. A. Villarma and J. S. Galang (*J. Philipp. Is. med. Ass.*, 1930, 10, 311) found no ill effects to either mother or foetus following immunization of pregnant women during a typhoid epidemic. In neither case, however, does the procedure convey immunity to the child, which has to be protected independently after birth.

Bilateral Pulmonary Cysts

Q.—A patient has bilateral pulmonary cysts, and it has been suggested that a phrenic nerve avulsion would lead to healing of these cysts. He has a poor chest expansion and also some muco-purulent sputum at times. Have you any information about the end-results of this operation in such a case?

A.—The use of phrenic paralysis in cystic conditions of the lung must be regarded at present as a method which may be tried in a very few special types of case, but not as an established therapeutic procedure. Some types of pulmonary cyst, congenital and acquired, enlarge by becoming inflated by air as a consequence of valvular mechanisms in their bronchial communications. This applies especially to those which arise peripherally in the broncho-pulmonary tree and approximate to bullous emphysema. In certain cases of this type where symptoms are produced by inspiratory inflation of a localized cyst or cysts, especially at the base of the lung, some benefit has been claimed from phrenic paralysis. This, by diminishing the force of inspiration, and possibly also by altering the position of the cyst in relation to the hilum of the lung and hence the conformation of its bronchial communication, may interfere with the mechanism by which the cyst becomes inflated, and thereby relieve those symptoms which arise from over-inflation of the cyst. If the condition is accurately described as a cyst, there can be no question of its "healing," since there is an epithelial lining which effectively prevents obliteration. The factors concerned in these cases are so difficult to evaluate that the brief account of the case given in the question is not enough to permit a dogmatic opinion on the likelihood of benefit resulting from phrenic paralysis, though the following observations can be made. With bilateral cysts it seems unlikely that phrenic paralysis will be beneficial, unless symptoms are being produced by recurrent or persistent inflation of the cyst or cysts on one side only. In the unlikely event of this being the case, a temporary paralysis of the phrenic nerve by crushing might be tried on the side on which the over-inflation occurs; permanent paralysis without a preliminary trial of temporary paralysis would be very unwise.

It will be clear from the foregoing account that phrenic paralysis can be expected to relieve only symptoms due to inflation of the cyst, such as paroxysmal increase in dyspnoea; it could do nothing for constant dyspnoea on exertion or for such symptoms as cough and expectoration. The account of the case given suggests that there may be a considerable degree of generalized emphysema, or widespread cystic change which would preclude radical surgical treatment. If this is not so, and the parts of the lungs not occupied by the cysts are normal, resection of the pulmonary segments containing cysts might be considered, even though this might involve operations on both sides of the chest.

Pediculosis Pubis

Q.—What is the most effective treatment of pediculosis pubis?

A.—If the hair is shaved off, only soap and water are necessary. If the hair is not removed, 2% D.D.T. in an emulsion is effective.

Non-specific Urethritis

Q.—(a) What treatment is most likely to cure non-specific urethritis of virus origin in a male? (b) What percentage of success is claimed for neoarsphenamine? (c) What is the likelihood of relapse after alcohol or exercise? (a) What is the corresponding condition in the female? An unmarried man aged 29 has non-specific urethritis. As his reactions to the Wassermann, Kahn, and gonococcal complement-fixation tests, and a prostatic smear, are all negative, the condition was presumed to be of virus origin. It cleared up after treatment with sulphadiazine, abstinence from alcohol and exercise, mist, sod. cit. et hyoseyam., and large quantities of fluids, but relapsed. For the last two months there has been only slight discharge at the end of micturition, usually aggravated by alcohol.

A.—(a) Streptomycin appears to be the most effective anti-viral agent, so that it should be well worth trying, if available. (b) From time to time reports of successful treatment of non-gonococcal urethritis with neoarsphenamine have appeared, but the writer knows of no series of cases so treated, so that it is impossible to give a percentage figure. (c) Either alcohol or exercise might cause a recurrence, the former because it is an irritant to the urethra, and the latter because inflamed tissues generally do better when placed at rest. (d) Presumably leucorrhoea in the female is the counterpart of non-gonococcal urethritis in the male; neither is a medical entity, and both are probably due to a variety of causes.

As regards the patient whose condition is described, it would be as well to carry out further investigations before resuming treatment. The urethral discharge and prostatic fluid should be examined microscopically and culturally; it may be that the condition is essentially a prostatorrhoea. If not, a urethroscopy should be done; if this shows a "sago-grain" urethritis, dilatation with a Kollmann's dilator should be carried out, followed by irrigation with mercury oxycyanide 1 in 6,000, once a week for several weeks or until the condition clears up. If a stricture is discovered, appropriate measures should be taken. If the above examinations are negative, no further treatment is indicated, since overactive treatment often tends to perpetuate signs and symptoms.

Oesophageal Stricture

Q.—A woman of 51 has had increasing oesophageal obstruction with frequent spasmodic complete blockage for the past eleven years. This was recently demonstrated radiologically as a tight stricture, with no ballooning above it, probably due to cicatrization of a peptic ulcer with no x-ray evidence of activity, though there is slight bleeding during oesophagoscopy and dilatation. The obstruction is $\frac{1}{2}$ inch (1.25 cm.) above the diaphragmatic aperture; there has never been actual pain, so that it is difficult to accept the peptic ulcer theory. Instrumental dilatation under general anaesthesia has given relief for only a day or two. Passage of bougies did not prevent complete closure by spasm at the following attempted meals. What further treatment is advised?

A.—The significant points in this case would appear to be: (a) The absence of any appreciable dilatation of the oesophagus as shown by a barium swallow; therefore cardiospasm is unlikely. (b) The generally good condition of the patient after eleven years' history, practically ruling out neoplasm. (c) The presence of a stricture in the last inch of the oesophagus, which is resistant to dilatation—suggesting an organic aetiology, which, in the absence of other history, points to a peptic ulcer. Such ulcers can exist without appreciable pain, but after such a long history anything other than excision is unlikely to yield results. Fibrosis and peri-oesophagitis occur just as with other peptic ulcers. For this reason cauterization of the stricture seems definitely contraindicated. In view of the facts (1) that all other methods have received a more than fair trial, (2) that the patient's general condition makes her a good operative risk,

(3) that the lesion is situated in the optimal position for comfortable surgical technique, and (4) that surgery for oesophageal lesions (with suitable anaesthetic methods) has in latter years become a reasonably safe procedure, excision of the stricture and oesophago-gastrostomy would seem to be strongly indicated.

Sacral Oedema

Q.—(1) What level of thrombosis in the inferior vena cava will produce sacral oedema? (2) What is the commonest cause of sacral oedema?

A.—(1) Thrombosis of the inferior vena cava would not cause sacral oedema alone, but only as part of a general oedema below the umbilicus.

(2) The common cause of sacral oedema is prolonged sitting-decubitus necessitated by illness. Any illness for which a patient has to be kept in bed for a long period may lead to the development of sacral oedema.

NOTES AND COMMENTS

Oestrogen Therapy of Menorrhagia.—Dr. G. I. M. SWAYNE (London, W.C.1) writes: In reply to a question regarding oestrogen therapy for prolonged and heavy uterine bleeding ("Any Questions?" April 23, p. 736), the statement is made that "... it is emergency treatment in that it controls the bleeding by raising the oestrogen level above the bleeding threshold. There is still the problem of preventing or controlling oestrogen withdrawal haemorrhage, which is likely to occur when treatment is suspended." These remarks are unjustified, and show little grasp of the true place of oestrogens in the treatment as well as the control of so-called functional uterine bleeding. Indeed, the initial control is merely the commencement of treatment, the essence of which consists in the production of regular withdrawal bleedings (which are not "haemorrhages" in the sense of uncontrolled floodings). In the climacteric phase the judicious continuation of this treatment with gradual reduction in dosage is frequently sufficient to produce a calm and satisfactory menopause. In the reproductive years, however, treatment cannot claim to have produced a cure without having re-established ovulation, and there is no doubt that with the proper dosage of oestrogens and, later, of oestrogens and progestogens, ovulation can be induced in an encouraging number of patients treated in this way. It is on these grounds that I would regard treatment with oestrogens as being something more than merely palliative or "emergency"; in many cases it is truly curative.

Granuloma Annulare.—Dr. F. PIERS (Nairobi) writes: In "Any Questions?" (March 12, p. 464) a correspondent asks about the modern treatment of granuloma annulare. For some obscure reason this condition is not uncommon here. I have found that infiltration of the lesions with a 2% solution of procaine (without adrenaline) in most cases results in a complete disappearance of the plaques. The amount of fluid one has to inject varies according to the size of the lesions, and some force is usually required to get the fluid in, and under, the hard plaques. But the method is easy to apply and entirely innocent. The rationale of this treatment is perhaps that lymphatic drainage is facilitated, and the quick and complete disappearance of the disk-like infiltrations supports this view.

Convulsions.—Dr. ERNST GUTHANER (Gatton, Queensland) writes: The answer given to the inquirer on convulsions ("Any Questions?" March 12, p. 463) mentions the traditional hot bath, though apparently irrelevant, as useful in occupying the mother until the arrival of the doctor or the spontaneous end of the convulsions. This hot bath, often reinforced by mustard, is absurd when the convulsions are brought on by pyrexia as the forerunner of infection, and can be decidedly harmful. The writer has seen one case where after a hot mustard bath the child was brought to the surgery with a hyperpyrexia of 105° F. (40.6° C.). It was limp, comatose, and died after a few hours in hospital. It is more rational to bring the temperature down in these cases by lukewarm sponges or antipyretics. On no account should they be given a hot bath, as it is against the dictum of *nil nocere*.

SUPPLEMENT TO THE BRITISH MEDICAL JOURNAL

LONDON SATURDAY MAY 21 1949

THE SECRETARY REPORTS

THE AMENDING BILL

Just before the Special Representative Meeting held in May, 1948, the Minister promised that he would include in the Amending Bill the following provisions:

(1) Whatever clarification of the position of partnerships may be found necessary in the light of the report of the Legal Committee which is now examining that question; so far as is at all practicable, this clarification will be made to operate retrospectively to July 5.

(2) Provision to make clear that a whole-time salaried general medical service cannot be introduced by regulations—i.e., would need a further Act of Parliament. This would include provision precluding the imposition by regulation of any universal full-time consultant service.

(3) Provision for executive councils to have the right to select their own chairmen, after the term of office of the present chairmen expires in March next.

(4) Provision to enable the professional member of the tribunal to be one of a panel of available members and not a fixed individual—so that the member may in each case be suitable in experience and otherwise to the particular issue before the tribunal.

(5) Power to the executive councils, where the local practitioners agree, to cover the costs of the local medical committee (by the necessary deduction from the practitioners' remuneration).

The Amending Bill which has just been presented to Parliament gives effect to the recommendations of the Legal Committee on Partnerships; prohibits a full-time salaried general practitioner service (with an exception for "special circumstances"); precludes the imposition by regulation of any universal whole-time specialist service; gives executive councils the right to select their own chairman and to determine his term of office; provides for the professional member of the tribunal to be selected from a panel of available members, and empowers executive councils, on the request of the local medical, dental, or pharmaceutical committee, to make deductions from the remuneration of doctors, dentists, or chemists to defray the administrative expenses of those local professional committees.

In addition to these amendments which had been promised by the Minister the Bill contains certain other proposals, including:

1. Clarification of the position obtaining under agreements between principals and assistants. The Legal Committee on Partnerships made no recommendation on this point, but expressed the view that the relationship between principal and assistant seemed to be analogous to that of partners, adding that "it would seem that the Act may cause considerable hardship to such assistants if no protection is afforded."

2. Under Section 12 of the Amending Bill any difference or dispute arising in respect of remuneration or conditions of service of those employed or engaged in the new Service is deemed to be a trade dispute within the meaning of the Industrial Courts Act, 1919, and to be a difference or dispute to which the Conciliation Act, 1896, applies. In effect this means that, where a dispute exists or is apprehended, either party may report it to the Minister of Labour and National Service and he may refer it, if both parties consent, to an Industrial Court for settlement. On the other hand, if both parties do not consent, he may refer it to the Industrial Court for advice. The composi-

tion of the Industrial Court is prescribed by the 1919 Act. The Minister of Labour and National Service appoints an independent president or chairman and also appoints a panel of other persons, some independent and others representing employers and workers respectively, to be members of the Court. The members to sit as the Court on any particular occasion are selected from this panel by the president.

This proposal deserves careful scrutiny. At first sight it seems to me that only where the Minister agrees can arbitration take place, and where he does not so agree all that can happen is that an outside body, set up for the purpose, gives advice. This proposal appears to fall short of the original Whitley proposal that in the event of disagreement being registered recourse could be had to arbitration whether the other side agreed or not.

3. The omission in the original Acts of any provision for the removal from the lists of executive councils of doctors, dentists, or chemists who have ceased to provide services in the areas concerned is rectified.

4. The extension from two months to three months of the period within which doctors called in by midwives under the Midwives Act, 1918, are required to submit their account to the local supervising authority for payment. For many years the profession has been seeking an extension of the two-month time limit.

With the exception of these last two items (3 and 4) none of the additional points which have been pressed upon the Ministry by the General Medical Services Committee and by the Joint Committee for Consultants and Specialists are included in the Bill.

Review of Hospital Staff—Right of Appeal

During the past few months professional review committees have been assessing the status of members of existing hospital medical staffs with a view to advising Boards which practitioners should be offered permanent contracts as specialists. The work of these review committees is now nearing completion and in some regions the result has already been notified to individual practitioners.

The issue is one of vital importance to all those who are adversely affected by the decision of a review committee, yet there is no right of appeal from the assessment except to the body which made it. The principle which the Central Consultants and Specialists Committee seeks to establish is that aggrieved practitioners should be given a right of appeal to an independent body. The committee—through the Joint Committee—has consistently pressed the Ministry to establish a professional appeal committee for this purpose. This right of appeal is regarded by the committee as of fundamental importance.

Practitioners who claim specialist status and who are aggrieved at their assessment should at once appeal to the Regional Hospital Board or Board of Governors concerned. They are also invited to inform the secretary of the Central Consultants and Specialists Committee (B.M.A. House, Tavistock Square, W.C.1), so that the committee may be in a position to assess the size of the problem. Clearly the Central Consultants and Specialists Committee could not be expected to judge the merits of individual cases, nor could such an expression of opinion be of any practical value to the practitioner.

NATIONAL HEALTH SERVICE (AMENDMENT) BILL

FINANCIAL MEMORANDUM

Part I of the Bill clarifies the position of general medical practitioners practising in partnership.

Clause 1 (5) provides that, as between partners who are taking part in the new Service and whose partnership agreement provides for options or obligations to purchase shares in the goodwill of the practice from one another, such shares shall be transferred in accordance with the terms of the agreement, except as to the payment of the purchase price, and as soon as possible after the completion of the transfer the appropriate amount of compensation shall be paid in full discharge of the purchase price.

This provision will not impose any additional charge on the Exchequer, but, as the compensation is normally payable only on the death or retirement of the practitioner concerned, it has the effect of accelerating payment in these cases.

Clause 1 (7) and (8). Clause 1 (8) provides that a doctor who joined the Service on the appointed day, and who is later required or exercises an option under the terms of a partnership agreement to purchase the share of a doctor who had not entered the service on that day, shall be entitled to compensation in respect of that share. This compensation will be paid out of moneys provided by Parliament but will be additional to the £66 million provided under Section 36 of the National Health Service Act, 1946. Under Clause 1 (7), however, compensation is not payable in respect of the share in a practice owned by a doctor in the Service which is purchased by a partner not in the Service, and the sum of £66 million will be diminished accordingly.

The amount of compensation which will not be payable by reason of the provision of Clause 1 (7) will be a set-off against the additional money which may become payable under Clause 1 (8), but it is not possible to say whether there will be a balance. It is estimated that about 50 practices are involved and that the number of doctors concerned is nearly 150.

Clause 6 deals with the position of assistants to doctors who joined the Service by the appointed day, and provides for payment of compensation to a principal in lieu of the purchase price in a case where an assistant who is providing general medical services under the Act of 1946 or the National Health Service (Scotland) Act, 1947, is required or exercises an option under his agreement with the principal to purchase the goodwill or part of the goodwill of the practice (Clause 6 (3)). No additional expenditure will be incurred, but the payment of compensation will be accelerated.

Clause 6 (5) provides that where an assistant who is not providing general medical services in pursuance of an option purchases the whole or part of the goodwill of his principal compensation shall not be payable in respect of that goodwill or the part thereof which is purchased. Here again the global sum of £66 million will be diminished, but it is not possible to say by how much.

Clause 7 provides that every partnership agreement or agreement between principal and assistant shall be deemed to contain a provision enabling any person who was a party to the agreement immediately before the appointed day and who claims that he has suffered or will suffer hardship as a result of the operation of the Act of 1946 or of the Act of 1947, or of this Bill, or of the regulations governing the calculation of compensation under Section 36 of the Act of 1946 or Section 37 of the Act of 1947, to refer the matter to the arbitration of an arbitration committee consisting of an arbitrator appointed by the Lord Chancellor or by the President of the Court of Session, a medical practitioner appointed by the President of the British Medical Association, and a qualified accountant appointed by the Minister or by the Secretary of State. The expenses of the Committee, including the remuneration and allowances payable to the member, will be met out of moneys provided by Parliament. The number of cases referred to the Committee is likely to be very small and the expenditure insignificant.

Clause 17 provides for payments by local health authorities of remuneration and expenses to medical practitioners who examine persons for the purposes of Sections 11 and 16 of the Lunacy Act, 1890, of the Mental Deficiency Act, 1913, or of Section 1 (2) or 5 of the Mental Treatment Act, 1930.

Provision is made in the Schedule to the Bill for payments to medical practitioners for the notification to local health authorities of certain diseases.

Most local health authorities are already making payments for the examinations referred to in Clause 17 and for the notification of infectious diseases, and the additional expenditure to be incurred will be very small. Under the provisions of section fifty-three of the Act of 1946 as amended by section seven of the Local Government Act, 1948, and the provisions of section fifty-three of the Act of 1947 as amended by section twenty-three of the Local Government Act, 1948, 50% of the cost will be borne by the Exchequer.

Clause 19 empowers the Minister and the Secretary of State to recover costs of maintenance from inmates of hospitals who are absent during the day from hospitals in which they are resident for the purpose of engaging in employment for which remuneration is received. It is not possible to estimate the amount which may be recovered.

The Schedule also amends the provisions of the Act of 1946 and of the Act of 1947 relating to the payment of travelling and subsistence allowances and for the loss of remunerative time to members of the several statutory bodies set up under the Act of 1946 and the Act of 1947, bringing those provisions into line with those relating to members of local authorities under the Local Government Act, 1948. The additional expenditure is likely to be very small.

Provision is also made in the Schedule for payments by Regional Hospital Boards, Boards of Governors of Teaching Hospitals, Hospital Management Committees, and Boards of Management of subscriptions to any association whose objects are approved by the Minister or the Secretary of State. The expenditure involved will be very small.

PART I

MEDICAL PARTNERSHIPS

1.—(1) This section applies to any partnership agreement in force on and immediately before the appointed day between medical practitioners one at least of whose names was entered on that day on a list of medical practitioners undertaking to provide general medical services.

(2) In this section:

the expression "listed partner" means a partner whose name was entered on the appointed day on a list of medical practitioners undertaking to provide general medical services;

the expression "new listed partner" means a partner whose name was not entered on such a list as aforesaid on the appointed day but has been so entered before the relevant date;

the expression "outside partner" means a partner whose name was not entered on any such list as aforesaid on the appointed day and has not been so entered before the relevant date;

and each of the said expressions shall, in the case of a deceased person who immediately before his death was a listed partner, a new listed partner, or an outside partner, be construed, where the context so requires, as referring to the personal representative of that person.

For the purpose of the aforesaid definitions the relevant date shall, in relation to any obligation imposed or option conferred on any such partner by the partnership agreement, be deemed to be the date on which the obligation is required to be performed or would but for this section be required to be performed, or, as the case may be, the date on which the option is first exercisable.

(3) Section thirty-five of the National Health Service Act, 1946 (hereafter in this Act referred to as "the Act of 1946"), which prohibits the sale of medical practices, shall not affect, and shall be deemed never to have affected, the exercise or performance under any partnership agreement to which this section applies of any right or obligation of a partner to sell to, or purchase from, another partner any share in the goodwill of the partnership practice, but any such agreement shall have effect subject to the following provisions of this section.

(4) Notwithstanding anything in section thirty-six of the Act of 1946 or in the last preceding subsection:

(a) there shall be determined in accordance with regulations made under the said section thirty-six the compensation payable in respect

of any share of the goodwill of the partnership practice carried on under any agreement to which this section applies, in all respects as if the said section thirty-five of the Act of 1946 prohibited the sale of any such share, whether under the agreement or otherwise; and

(b) the payment of the compensation so determined and of interest thereon shall be subject to the following provisions of this section.

(5) Where any agreement to which this section applies imposes an obligation or confers an option on a listed or new listed partner to purchase the share of another partner being a listed partner in the goodwill of the partnership practice, and, in the case of an option, the option has been exercised, that share shall be transferred at the time and on the terms (except as to the payment of the purchase price) provided in the agreement, and there shall be paid to the partner from whom the share is transferred, on or as soon as possible after the completion of the transfer, in complete satisfaction of the purchase price, the compensation determined as aforesaid in respect of that share.

(6) Where any agreement to which this section applies:

(a) imposes an obligation on an outside partner to purchase the share of a listed partner or a new listed partner in the goodwill of the partnership practice; or

(b) imposes an obligation on a new listed partner to purchase the share of another new listed partner in the goodwill of the partnership practice;

the obligation shall be deemed to be an option exercisable by notice in writing to purchase that share not later than three months after the time at which, and otherwise on the same terms as those on which, the obligation would have had to be performed.

(7) Where the share of a listed partner in the goodwill of the partnership practice carried on under any agreement to which this section applies has been purchased by an outside partner in pursuance of an option conferred by the last preceding subsection or by the agreement, the compensation determined as aforesaid in respect of that share shall not be paid and the interest thereon shall cease to be payable as from the date when the option was exercised:

Provided that the amount of compensation payable in respect of any other medical practice or share thereof under section thirty-six of the Act of 1946 shall not be increased in consequence of the said compensation not being paid.

(8) Where the share of an outside partner or new listed partner in the goodwill of the partnership practice carried on under any agreement to which this section applies has been purchased by a listed partner in pursuance of an obligation imposed or option conferred by the agreement, there shall be paid to the listed partner out of moneys provided by Parliament (but not as part of the compensation payable under section thirty-six of the Act of 1946) compensation of an amount bearing to the compensation determined under subsection (4) of this section in respect of the share of the listed partner in such goodwill the same proportion as the share of the outside partner or, as the case may be, new listed partner in such goodwill bears to the said share of the listed partner:

Provided that:

(a) if the compensation payable under this subsection exceeds the purchase price, the compensation shall be reduced by the amount of the excess;

(b) if the share purchased is that of a new listed partner, and the purchase price exceeds the amount of the compensation payable to the listed partner under this subsection, the amount of that excess shall be deducted from the purchase price and, if already paid, shall be repaid;

(c) this subsection shall not apply in a case where at the time of the purchase or, if the listed partner has died before the time of the purchase, at the time of his death, the name of the listed partner is or was no longer entered on such a list as aforesaid.

(9) The compensation payable under the last preceding subsection shall be payable at or as soon as possible after the time when the purchase price for the said share is paid:

Provided that, if the purchase price is payable by instalments, the said compensation shall be payable at such times and in such manner as may be prescribed.

(10) Where an agreement to which this section applies provides for the purchase of a part of any partner's share in the goodwill of the partnership practice by another partner, the preceding provisions of this section shall have effect, in relation

to that purchase and to any right or obligation in respect thereof, as if references to a share of such goodwill were construed as references to a part of such a share and as if references to the compensation determined in respect of such a share were construed as references to a proportionate part of that compensation.

(11) Where an agreement to which this section applies provides for the purchase of a share or part of a share in the goodwill of the partnership practice by two or more partners, the agreement shall have effect for the purposes of this section as if it provided for the separate purchase by each of those partners of such part of that share as will, in accordance with the agreement, be added to the existing share of that partner after the purchase, and the preceding provisions of this section shall apply accordingly.

(12) Where any agreement to which this section applies contains provisions which take effect on the purchase of any share or part of a share of the goodwill of the partnership practice, those provisions shall take effect in like manner on the transfer of that share or part in accordance with this section, notwithstanding that the transfer does not constitute a purchase.

(13) For the purposes of this section and the following provisions of this Act relating to medical partnerships, a member of a medical partnership shall, if the partnership agreement defines his share in the goodwill of the partnership practice and distinguishes that share from his share in the profits of the partnership, be deemed to have the share in the goodwill so defined, and in any other case his share in that goodwill shall be deemed to be the same as his share in the profits of the partnership:

Provided that, if the partnership agreement contains a provision which was in force immediately before the appointed day and divides into shares the aggregate compensation payable in respect of the goodwill of the partnership practice or, as the case may be, payable in respect of the shares in that goodwill of the persons entitled to such compensation, that provision shall be deemed to effect a corresponding division of the goodwill of the partnership practice or, as the case may be, the aggregate of those shares therein.

2. Where any partnership agreement to which the last preceding section applies is subsequently modified or is replaced by a subsequent agreement, the agreement as so modified or, as the case may be, the new agreement shall, so long as at least two of the partners to whom the agreement relates were partners under the original agreement on and immediately before the appointed day, be deemed for the purposes of the last preceding section to be the original agreement, and any subsequent modification or replacement shall be treated in like manner so long as the condition aforesaid remains satisfied:

Provided that the last preceding section shall only apply in relation to the purchase, and rights and obligations in respect of the purchase, of a share in the goodwill of a medical partnership carried on under any such agreement, if the persons who are or would be parties to the purchase were members of the partnership on and immediately before the appointed day and the provisions of the agreement relating to the purchase are substantially the same as they were immediately before the appointed day.

3.—(1) Where any medical practitioner was practising in partnership on and immediately before the appointed day but did not make an application before the appointed day for inclusion in a list of medical practitioners undertaking to provide general medical services, he shall, if he has made or makes on or at any time after the appointed day and before the expiration of the period of two months beginning with the date of the passing of this Act an application in the prescribed manner to the Executive Council for any area in which he was practising on the appointed day, be entitled to be included in the list of medical practitioners undertaking to provide general medical services for persons in that area, and section thirty-four of the Act of 1946 shall not apply to any such application and, if any such application made before the passing of this Act has been refused, the refusal shall not have effect and the application shall forthwith be granted.

(2) For the purposes of section thirty-six of the Act of 1946 (which provides for the payment of compensation for the loss of rights to sell medical practices), any medical practitioner who was practising in partnership on the appointed day and

whose name was subsequently, but before the expiration of the period aforesaid, entered on any such list as aforesaid (whether by virtue of the preceding subsection or otherwise) shall be treated in like manner as if his name had been so entered on the appointed day, and compensation shall be determined in respect of his share of the goodwill of the partnership practice as at the appointed day.

(3) This Part of this Act shall apply, and shall be deemed always to have applied, to any such medical practitioner, and to the partnership agreement under which he carried on his practice on and immediately before the appointed day, in like manner as if his name had been entered as aforesaid on the appointed day, and he shall be deemed, for the purposes of section one of this Act, to be a listed partner and not to be a new listed partner.

4.—(1) Section one of this Act shall apply in relation to rights and obligations which were exercised or performed, or were required to be exercised or performed, on or after the appointed day and before the passing of this Act, under an agreement to which that section applies, subject to the following modifications:

(a) for subsection (5) there shall be substituted the following subsection:

"(5) Where, under an agreement to which this section applies, the share of a listed partner in the goodwill of the partnership practice has been purchased (whether before or after the passing of this Act) by another listed partner, the compensation determined under subsection (4) of this section in respect of that share shall be paid as soon as possible after the completion of the transfer of the share or the passing of this Act (whichever is the later), to the partner by whom it was purchased:

Provided that if the amount of the compensation exceeds the purchase price the excess shall be paid to the partner whose share was purchased";

(b) subsection (6) shall not apply;

(c) in subsection (7), the reference to an option conferred by the agreement shall include a reference to an obligation imposed by the agreement, and the reference to the rate when the option was exercised shall be construed as a reference to the passing of this Act;

(d) the reference in subsection (9) to the time when the purchase price is paid shall be construed as a reference to that time or the passing of this Act, whichever is the latter; and

(e) for subsection (11) the following subsection shall be substituted:

"(11) Where an agreement to which this section applies provides for the purchase of a share or part of a share in the goodwill of the partnership practice by two or more partners, any purchase made in pursuance of such a provision shall be treated for the purposes of this section as if it were two separate purchases by the two respective partners of such parts of that share as will, in accordance with the agreement, be added to the existing shares of those partners after the purchase, and the preceding provisions of this section shall apply accordingly."

(2) The preceding subsection shall, in relation to any agreement which, by virtue of subsection (3) of the last preceding section becomes, at any time after the passing of this Act and before the expiration of the period of two months beginning with the date of the passing of this Act, an agreement to which section one of this Act applies, have effect as if the references to the passing of this Act were references to the date on which the agreement becomes an agreement to which that section applies.

5.—(1) Where, in the case of a medical partnership carried on under an agreement in force on and immediately before the appointed day, the name of none of the partners has, before the expiration of the period of two months beginning with the date of the passing of this Act, been entered on a list of medical practitioners providing general medical services, but the name or names of one or more of the partners has or have subsequently been entered on such a list, section thirty-five of the Act of 1946 shall not affect, and shall be deemed never to have affected, the exercise or performance under the agreement of any right or obligation of a partner to sell to, or purchase from, another partner any share in the goodwill of the partnership practice, but any such agreement shall have effect subject to the next following subsection.

(2) Where any such agreement imposes an obligation on a partner whose name has not, at the time when the obligation would have had to be performed, been entered on any such list as aforesaid, to purchase the share or any part of the share

of any such partner whose name has been so entered in the goodwill of the partnership practice, the obligation shall be deemed to be an option exercisable by notice in writing to purchase that share not later than three months after the time at which, and otherwise on the same terms as those on which, the obligation would have had to be performed.

6.—(1) Where an agreement in force on and immediately before the appointed day provides for the performance of services by a medical practitioner thereafter in this section referred to as "the assistant") as an assistant to another medical practitioner (hereafter in this section referred to as "the employer"), and the name of the employer was on the appointed day, or has subsequently been, entered on a list of medical practitioners providing general medical services, section thirty-five of the Act of 1946 shall not affect, and shall be deemed never to have affected, the exercise or performance of any right or obligation conferred or imposed by the agreement on the assistant to purchase the goodwill or any part of the goodwill of the practice of the employer, or any right or obligation conferred or imposed by the agreement on the employer or his personal representative to sell the goodwill of his practice or any part thereof to the assistant, but any such agreement shall have effect subject to the following provisions of this section.

(2) Where, in the case of any such agreement, the name of the employer was entered on the appointed day on a list of medical practitioners undertaking to provide general medical services, then, notwithstanding anything in section thirty-six of the Act of 1946 or in the preceding subsection:

(a) there shall be determined in accordance with regulations made under the said section thirty-six the compensation payable in respect of the goodwill of the practice of the employer, in all respects as if the said section thirty-five of the Act of 1946 prohibited the sale of that practice, whether under the agreement or otherwise; and

(b) the payment of the compensation so determined and of interest thereon shall be subject to the following provisions of this section.

(3) Where any agreement to which the last preceding subsection applies imposes an obligation or confers an option on the assistant to purchase the goodwill of the practice of the employer or any part thereof and, in the case of an option, the option is exercised, that goodwill or part shall, if the name of the assistant has, before the time when the obligation is required to be performed or the option is first exercisable, been entered on a list of medical practitioners undertaking to provide general medical services, be transferred to him at the time and on the terms (except as to the payment of purchase price) provided in the agreement, and there shall be paid to the employer or his personal representative, on or as soon as possible after the completion of the transfer, in complete satisfaction of the purchase price, the compensation determined as aforesaid in respect of the goodwill of his practice or, in the case of the transfer of a part of that goodwill a proportionate part of that compensation.

(4) Where any agreement to which subsection (2) of this section applies imposes an obligation on the assistant to purchase the goodwill of the practice of the employer or any part thereof and the name of the assistant has not, before the time when the obligation would have had to be performed, been entered on such a list as aforesaid, the obligation shall be deemed to be an option exercisable by notice in writing to purchase the goodwill or part not later than three months after the time at which, and otherwise on the same terms as those on which, the obligation would have had to be performed.

(5) Where the goodwill of the practice of the employer or any part thereof has been purchased by the assistant in pursuance of an option conferred by the last preceding subsection or in pursuance of an option conferred by the agreement and exercised at a time when the assistant was not entered on such a list as aforesaid, the compensation determined under subsection (2) of this section in respect of that goodwill, or as the case may be, a proportionate part of that compensation, shall not be paid and, in so far as it has been paid, shall be repaid to the Minister, and the interest on the compensation shall cease to be payable as from the date when the option was exercised:

Provided that the amount of compensation payable in respect of any other medical practice or share thereof under section thirty-six of the Act of 1946 shall not be increased in consequence of the said compensation not being paid.

SAFE Persomnia OR BARBITURATES?

The frequently reported losses of barbiturates announced by the B.B.C. are considered to be, more often than not, attempts by addicts to obtain additional supplies of the drug. The medical profession is therefore rightly reluctant to prescribe this drug frequently or for long periods.

The best means to stop such undesirable practice is to restrict prescriptions of barbiturates to cases which are not likely to respond to other sedatives or hypnotics.

Persomnia, a combination of two *open-chain ureides**—bromisovalerylurea and carbromal—has been proved by long clinical practice to be as effective as barbiturates in practically all cases in which a sedative or mild hypnotic is indicated. The preparation discloses a marked synergistic enhancement of effect as compared with the therapeutic value of the two component drugs *individually* employed.

*Barbiturates are closed-chain ureides

Some of the advantages of PERSOMNIA over barbiturates are the following:

- Safety in use, even in doses largely in excess of therapeutic requirements
- Not habit-forming
- No after-effects
- No effect on the normal circulation
- Minimal risk of bromism
- No cumulative action
- Well tolerated
- Rapid absorption and excretion
- Induces quiet sleep without preliminary excitement

NOTE:—Persomnia has no official B.P., B.P.C., or N.(W.)F. equivalent.

Free clinical samples and literature will be gladly sent on request.

Child Nutrition

It is now recognized that diet plays an important role in the health and development of children, and that good nutrition is particularly vital during the early years of life. Among the nutrients known to be essential for the maintenance of health are the vitamins of the B₂ complex.

One of the most useful, natural dietary sources of the B₂ vitamins is to be found in Marmite, which is a concentrated yeast extract. It has been shown that the systematic inclusion of Marmite in the diet is especially beneficial for expectant and nursing mothers, and for babies. Marmite is also ordered extensively for children of all ages.

MARMITE yeast extract

contains

Riboflavin (vitamin B₂) 1.5 mg. per oz.
Niacin (nicotinic acid) 16.5 mg. per oz.

Jars: 1-oz. Bd., 2-oz. 1/1, 4-oz. 2/-, 8-oz. 3/3, 16-oz. 5/9

Obtainable from Chemists and Grocers

Special terms for packs for hospitals, welfare centres and schools

VASANO

for the prevention and treatment of

'Vasano' consists of

a mixture of hyoscine, hyoscyamine and camphoric acid in balanced combination which affords optimal central and peripheral action. Hyoscine, acknowledged as one of the most effective single agents for the prevention of travel sickness, exerts a sedative influence on the higher centres and is a parasympathetic depressant, while hyoscyamine acts peripherally upon the vagus.

'VASANO' is a proven remedy for all forms of travel sickness, by land, sea or air, and is also widely prescribed for the treatment of Meniere's Disease.

12.—(1) Any difference or dispute arising with respect to the remuneration or conditions of service of persons employed or engaged in the provision of services under either the Act of 1946 or the Act of 1947 shall be deemed to be:

(a) a difference or dispute to which the Conciliation Act, 1896, applies; and

(b) a trade dispute within the meaning of the Industrial Courts Act, 1919.

(2) The power of the Minister of Labour and National Service under paragraphs (b) and (c) of subsection (2) of section two of the said Industrial Courts Act, 1919, to refer matters for settlement to the arbitration of one or more persons appointed by him or to a board of arbitration constituted in the manner specified in the said paragraph (c) shall be deemed, in the case of any such difference or dispute as aforesaid, to include power to refer the matter for advice to one or more persons appointed by him or to such a board of arbitration, and subsection (3) of section three of the said Act (which excludes the Arbitration Act, 1889, in relation to the references therein mentioned) shall extend to any reference made by virtue of this subsection.

13.—(1) Subsection (2) of section thirty-three of the Act of 1946 and subsection (2) of section thirty-four of the Act of 1947 (which enable regulations to be made with respect to the provision of general medical services) shall be amended by the addition at the end of each of those subsections of the following paragraph:

"(c) for the removal from the list of medical practitioners undertaking to provide general medical services for persons in any area of the name of a medical practitioner in whose case it has been determined in such manner as may be prescribed that he has never provided or has ceased to provide general medical services for persons in that area."

(2) Subsection (2) of section thirty-eight of the Act of 1946 and subsection (2) of section forty of the Act of 1947 (which enable regulations to be made with respect to the provision of pharmaceutical services) shall be amended by the addition at the end of each of those subsections of the words "and

(c) for the removal from the list of persons undertaking to provide pharmaceutical services for persons in any area of the name of any person in whose case it has been determined in such manner as may be prescribed that he has never provided or has ceased to provide such services for persons in that area."

(3) Subsection (2) of section forty of the Act of 1946 and subsection (2) of section thirty-nine of the Act of 1947 (which enable regulations to be made with respect to the provision of general dental services) shall be amended by the addition at the end of each of those subsections of the following paragraph:

"(f) for the removal from the list of dental practitioners undertaking to provide general dental services for persons in any area of the name of a dental practitioner in whose case it has been determined in such manner as may be prescribed that he has never provided or has ceased to provide general dental services for persons in that area."

(4) Subsection (3) of section forty-one of the Act of 1946 and subsection (3) of section forty-two of the Act of 1947 (which enable regulations to be made with respect to the provision of supplementary ophthalmic services) shall be amended by the addition at the end of each of those subsections of the following paragraph:

"(d) for the removal from the list of medical practitioners, ophthalmic opticians or dispensing opticians undertaking to provide supplementary ophthalmic services for persons in any area of the name of a medical practitioner, ophthalmic optician, or dispensing optician, as the case may be, in whose case it has been determined in such manner as may be prescribed that he has never provided or has ceased to provide supplementary ophthalmic services for persons in that area."

14.—(1) The Seventh Schedule to the Act of 1946 (which relates to the constitution of the Tribunal established for the purpose of inquiring into cases that may involve the removal of any person from a list prepared under Part IV of the Act) shall have effect with the substitution for paragraphs 4 and 5 of that Schedule of the following paragraphs:

"4. The remaining member (hereinafter referred to as 'the practitioner member') shall be appointed by the Minister from such

one of the panels appointed as hereinafter provided as the Minister considers appropriate having regard to the profession or calling of the person whose case is being investigated.

For the purposes of this paragraph, the Minister shall, after consultation with such organizations as the Minister may recognize as representative of the several professions or callings concerned appoint the following panels, none of which shall exceed six persons—that is to say: (a) a panel of medical practitioners; (b) a panel of dental practitioners; (c) a panel of registered pharmacists; (d) a panel of medical practitioners having the qualifications prescribed under section forty-one of this Act; (e) a panel of ophthalmic opticians; and (f) a panel of dispensing opticians.

5. If any of the members of the Tribunal is unable to act in any case, a deputy may be appointed by the Lord Chancellor or the Minister as in the case of the appointment of the member in question and, if the member is the chairman, the deputy shall possess the professional qualifications required for the office of chairman, and if the member is the practitioner member, the deputy shall be appointed from the same panel."

(2) Nothing in this section shall affect the constitution of the said Tribunal for the purpose of inquiring into any case the inquiry into which has commenced before the passing of this Act.

(3) This section shall apply to Scotland with the substitution for references to section forty-one of and to the Seventh Schedule to the Act of 1946 of references to section forty-two of and to the Eighth Schedule to the Act of 1947 and for the expressions "Lord Chancellor" and "Minister," wherever they occur, of the expressions "Lord President of the Court of Session" and "Secretary of State" respectively.

15.—(1) It is hereby declared for the removal of doubts that any power conferred by the Act of 1946 to prescribe the qualifications to be possessed by any medical practitioner or ophthalmic or dispensing optician includes a power to prescribe: requirement that the practitioner or optician shall show, to the satisfaction of a committee recognized by the Minister for the purpose or to the satisfaction of the Minister acting on the advice of such a committee, that he possesses such qualifications including qualifications as to experience, as may be mentioned in the regulations.

(2) In the application of this section to Scotland for reference to the Act of 1946 and to the Minister there shall be respectively substituted references to the Act of 1947 and to the Secretary of State.

16. Notwithstanding anything contained in the constitution or rules of any voluntary organization formed for the purpose of providing a service of nurses for attendance on the sick in their own homes or of midwives, or in any trust deed or other instrument relating to any such organization or service, any property vested in the organization or held by any persons on trust for the organization or service or for any specific purposes connected with the organization or service may be transferred to: local health authority, on such terms as may be agreed between the authority and the organization or trustees, with a view to the property being used by the authority for purposes similar to the purposes for which it was previously used.

17.—(1) Where a medical practitioner:

(a) carries out a medical examination of any person with a view to an urgency order being made under section eleven of the Lunacy Act, 1890;

(b) is called in by a justice of the peace under section sixteen of the said Act and carries out a medical examination of any person brought before the justice under that section;

(c) carries out a medical examination of any person with a view to his being placed in or sent to an institution within the meaning of the Mental Deficiency Act, 1913; or

(d) carries out a medical examination of any person with a view to his treatment as a voluntary patient under subsection (2) of section one of the Mental Treatment Act, 1930, or his treatment as a temporary patient under section five of that Act;

the local health authority for the area where the person examined resides shall pay to that medical practitioner reasonable remuneration in respect of the said examination and in respect of any certificate or recommendation given by him with regard to the person examined and the amount of any expense reasonably incurred by him in connexion with the examination or the giving of any such certificates or recommendation:

Provided that:

(a) no payment shall be made under this subsection to a medical practitioner in respect of an examination carried out as part of his duty to provide general medical services for the person examined;

(6) this subsection shall only apply in a case where it is intended, when the medical examination is carried out, that, if an urgency order or a summary reception order is made or the person examined is placed in or sent to such an institution as aforesaid or is treated as a voluntary or temporary patient as aforesaid, the whole cost of his maintenance and treatment will be defrayed out of moneys provided by Parliament under the Act of 1946.

(2) Section two hundred and eighty-five of the Lunacy Act, 1890 (which provides for the payment of remuneration and expenses to medical practitioners called in under the said section sixteen, if the justice of the peace so orders), shall cease to have effect.

18.—(1) Where the Board of Control have, before the commencement of this Act, purported to make an order under subsection (2) of section eleven of the Mental Deficiency Act, 1913, providing for the continuance of any detention order, but the Board have failed to make the order within the time limited by the said section eleven, then, unless it is shown that the order purported to have been made under the said subsection (2) was not made in good faith, the detention order purported to have been continued shall be deemed not to have expired and to have been duly continued as if the order purporting to continue it had been made within the required time and otherwise in conformity with the provisions of the said section eleven.

(2) In this section the expression "detention order" means an order made under the Mental Deficiency Act, 1913, that a defective be sent to an institution for defectives, and the expression "institution for defectives" has the meaning assigned to it by that Act as amended by the Act of 1946.

19. Notwithstanding the provisions of subsection (2) of section one of the Act of 1946, or subsection (2) of section one of the Act of 1947, it shall be lawful, in the case of any person for whom the Minister or, as the case may be, the Secretary of State is providing hospital and specialist services as an in-patient and who is absent during the day from the hospital where he is a patient for the purpose of engaging in employment for which he is remunerated, for the Minister or Secretary of State to require that person to pay such part of the cost of his maintenance in the hospital and any costs incidental thereto, as may seem to the Minister or Secretary of State reasonable having regard to the amount of the remuneration, and the Minister or Secretary of State may recover the payment so required.

20.—(1) The amendments specified in Part I and Part II of the Schedule to this Act, being amendments of a minor character, shall be made in the Act of 1946 and the Act of 1947, respectively:

Provided that the amendments of the Fifth Schedule to the Act of 1946 and the Sixth Schedule to the Act of 1947 relating to the Chairman of an Executive Council shall, except in a case where the office of such a chairman is vacant at the passing of this Act, only take effect, in relation to each Executive Council, when the appointment of the person holding office as chairman at the date of the passing of this Act comes to an end.

(2) Subsection (2) of section fourteen of the Midwives Act, 1918, as amended by subsection (2) of section two of the Midwives and Maternity Homes Act, 1926 (which requires a medical practitioner called in to assist a midwife in case of emergency to submit within two months his claim for the payment of a fee by the local health authority), shall be amended by the substitution for the words "two months" of the words "three months."

(3) Section three of the Cancer Act, 1939 (which empowers the Minister to lend money to the National Radium Trust), shall cease to have effect.

(4) In the application of subsection (2) of this section to Scotland, for the references to subsection (2) of section fourteen of the Midwives Act, 1918, and to subsection (2) of section two of the Midwives and Maternity Homes Act, 1926, there shall be respectively substituted references to subsection (2) of section twenty-two of the Midwives (Scotland) Act, 1915, and to subsection (2) of section four of the Midwives (Scotland) Act, 1927.

21. (1) There shall be defrayed out of moneys provided by Parliament any increase attributable to the passing of this Act in any grants or sums payable under any other enactment out of moneys so provided.

(2) All sums received by the Minister or Secretary of State under this Act shall be paid into the Exchequer.

22. (1) In this Act:

the expressions "the Act of 1946" and "the Act of 1947" have the meanings assigned to them by section one and section nine of this Act respectively;

the expression "the appointed day" means the day appointed for the purposes of sections thirty-three to thirty-seven of the Act of 1946 and sections thirty-four to thirty-eight of the Act of 1947.

(2) Other expressions used in this Act shall, in the application of this Act to England and Wales, have the same meanings as in the Act of 1946 and, in the application of this Act to Scotland, have the same meanings as in the Act of 1947.

(3) Any reference in this Act to any other enactment shall be construed as a reference to that enactment as amended by any subsequent enactment including this Act.

23. (1) This Act may be cited as the National Health Service (Amendment) Act, 1949, and this Act, so far as it applies to England and Wales, and the Act of 1946 may be cited together as the National Health Service Acts, 1946 and 1949, and this Act, so far as it applies to Scotland, and the Act of 1947 may be cited together as the National Health Service (Scotland) Acts, 1947 and 1949.

(2) This Act shall not extend to Northern Ireland.

(3) Subsection (3) of section eighty of the Act of 1946 (which provides for the extension of that Act to the Isles of Scilly) shall have effect as if the references to that Act includes references to this Act.

SCHEDULE: MINOR AMENDMENTS OF THE ACTS OF 1946 AND 1947

PART I: MINOR AMENDMENTS OF THE ACT OF 1946

In subsection (2) of section five (which provides for the treatment, at hospitals providing hospital and specialist services, of the patients of medical practitioners on the staff of such hospitals), after the words "medical practitioner," wherever they occur, the words "or dental practitioner" shall be inserted.

In subsection (2) of section twenty-two (which empowers a local health authority to recover from persons availing themselves of maternity and child welfare services charges in respect of articles provided by the authority) for the words "any articles" there shall be substituted the words "residential accommodation, food, or articles."

In subsection (4) of section thirty-one (which empowers the Minister to establish a joint committee for the areas of two or more Executive Councils and to provide, in relation to that committee, for any of the matters for which, in relation to an Executive Council, regulations made under the Fifth Schedule to the Act may provide), for the words "matters for which, in relation to an Executive Council, regulations made under the Fifth Schedule to this Act may provide" there shall be substituted the words "matters for which, in relation to an Executive Council, provision is or may be made by or under the supplementary provisions of the Fifth Schedule to this Act."

At the end of section thirty-two (which relates to local representative committees) there shall be added the following subsections:

"(3) The Executive Council may, on the request of the Local Medical Committee or the Local Pharmaceutical Committee or the Local Dental Committee for their area, allot to that Committee out of the moneys available to the Council for the remuneration of persons of whom that Committee is representative and who provide general medical services, pharmaceutical services or, as the case may be, general dental services under this Part of this Act, such sums for defraying the administrative expenses of the Committee, including travelling and subsistence allowances payable to members of the Committee, as may be determined by the Executive Council with the approval of the Minister and the amount of any such sums shall be deducted in such manner as may be so determined with such approval, from the remuneration of the persons aforesaid.

(4) Any such Committee as aforesaid may, with the approval of the Minister, delegate any of their functions, with or without restrictions or conditions, to subcommittees composed of members of the Committee."

In subsection (5) of section fifty-four (which provides for defraying out of moneys provided by Parliament any payments

made in respect of loss of remunerative time or travelling or subsistence expenses to members of any body constituted under the Act) or the words "any loss of remunerative time or any travelling or subsistence expenses" there shall be substituted the words "any loss of earnings or additional expenses (including travelling and subsistence expenses)."

At the end of paragraph (h) of subsection (1) of section sixty-seven (which relates to the superannuation of, among others, officers of voluntary organizations providing services under certain enactments) there shall be added the words "or under Part III of the National Assistance Act, 1948."

In paragraph 2 of the First Schedule (which enables the Minister to make regulations for the making of payments to members of the Central Council and of standing advisory committees constituted under the Act and of committees and sub-committees set up under that Schedule in respect of loss of remunerative time and travelling and subsistence expenses) for the words "any loss of remunerative time or any travelling or subsistence expenses" there shall be substituted the words "any loss of earnings they would otherwise have made or any additional expenses (including travelling and subsistence expenses) to which they would not otherwise have been subject, being loss or expenses necessarily suffered or incurred by them for the purpose of enabling them to perform duties as members of the Central Council or standing advisory committee, or committee or subcommittee set up as aforesaid."

For sub-paragraph (c) of paragraph 2 of Part IV of the Third Schedule (which enables the Minister to make regulations for the making of payments to members of Regional Hospital Boards, Boards of Governors of teaching hospitals, and Hospital Management Committees in respect of loss of remunerative time or, if special circumstances justify it, in respect of travelling or subsistence expenses) there shall be substituted the following sub-paragraph:

"(c) for the making of such payments as may be prescribed to members of those bodies or committees in respect of

(i) any loss of earnings they would otherwise have made or any additional expenses (other than expenses on account of travelling or subsistence) to which they would not otherwise have been subject, being loss or expenses necessarily suffered or incurred by them for the purpose of enabling them to perform any approved duty; or

(ii) any travelling or subsistence expenses necessarily incurred by them for the purpose of enabling them to perform any approved duty required to be performed at a distance of more than three miles from their usual place of residence"

At the end of the said paragraph 2 there shall be added the following sub-paragraph:

"(e) for the payment by a Regional Hospital Board, Board of Governors of a teaching hospital or a Hospital Management Committee of such sums as may be approved by the Minister, as subscriptions to the funds of any association whose objects are approved by the Minister for the purpose of this sub-paragraph."

At the end of the said Part IV of the Third Schedule the following paragraph shall be added:

"(5) In this Schedule, the expression 'approved duty,' in relation to a member of a body corporate constituted under the foregoing provisions of this Schedule or any committee of that body, means any of the following duties—that is to say:

(a) attendance at a meeting of the body or any committee thereof;

(b) the doing of any other thing approved by the body for the purpose of, or in connexion with, the discharge of the functions of the body or any committee thereof;

(c) in the case of a member of the body, attendance as a representative of the body at a conference or meeting convened by one or more such bodies or by any association of such bodies."

Paragraph 1 of the Fifth Schedule (which relates to the constitution of Executive Councils) shall be amended as follows:

(a) for the words "a chairman appointed by the Minister and twenty-four other members" there shall be substituted the words "twenty-five members";

(b) in sub-paragraph (b), for the word "four" there shall be substituted the word "five";

(c) at the end of the paragraph, the following words shall be added: "The members of an Executive Council shall from time to time, in accordance with such procedure as may be prescribed, appoint one of their members to be chairman of the Council."

After paragraph 2 of the said Fifth Schedule there shall be inserted the following new paragraph:

"2A. The term of office of the chairman of an Executive Council shall be such as the Council, when making the appointment, determine:

Provided that if the chairman ceases to be a member of the Council he shall also cease to be chairman."

For sub-paragraph (c) of paragraph 3 of the said Fifth Schedule (which enables the Minister to make regulations for the making of payments to members of Executive Councils or committees thereof in respect of loss of remunerative time, or, if special circumstances justify it, in respect of travelling or subsistence expenses), there shall be substituted the following sub-paragraph:

"(c) for the making of such payments as may be prescribed to members of the Council or any such committee in respect of any loss of earnings they would otherwise have made or any additional expense (including travelling and subsistence expenses) to which they would not otherwise have been subject, being loss or expenses necessarily suffered or incurred by them for the purpose of enabling them to perform any approved duty."

In sub-paragraph (e) of the said paragraph 3 the words "and for the payment at the prescribed rates of any expenses reasonably incurred by representatives in attending meetings of any such association" shall be omitted.

At the end of the said paragraph 3 the following proviso shall be added:

"Provided that:

(i) a member of an Executive Council for the area of a local health authority who are the council of a county borough or a member of a committee appointed by such an Executive Council shall not be entitled to any payments under sub-paragraph (c) of this paragraph in respect of travelling and subsistence expenses in respect of a duty performed within the area of the Executive Council; and

(ii) a member of an Executive Council for the area of a local health authority who are the council of a county or for the area of two or more local health authorities or a member of a committee appointed by such an Executive Council shall not be entitled to any payments under the said sub-paragraph (c) in respect of travelling or subsistence expenses in respect of a duty performed within the area of the Executive Council except in respect of duties performed at a distance of more than three miles from his usual place of residence"

At the end of the said Fifth Schedule the following paragraph shall be added:

"7. In this schedule, the expression 'approved duty,' in relation to a member of an Executive Council or any committee thereof, means any of the following duties—that is to say:

(a) attendance at a meeting of the Council or of any committee thereof;

(b) the doing of any other thing approved by the Council for the purpose of, or in connexion with, the discharge of the functions of the Council or any committee thereof;

(c) attendance as a representative of the Council at a conference or meeting convened by one or more Executive Councils or by any association of Executive Councils whose objects are approved by the Minister."

The provision of the Tenth Schedule, which imposes a duty on medical officers of health who receive certificates or notices under certain sections of the Public Health Act, 1936, relating to infectious diseases, to send copies thereof within twelve hours after receipt to the local health authority, shall be amended as follows:

(a) after the words "a certificate or notice under section one hundred and forty-four, section one hundred and forty-six, or section two hundred and forty-two of the said Act" there shall be inserted the words "or in respect of a disease notifiable in accordance with regulations made under section one hundred and forty-three of the said Act";

(b) for the words "within twelve hours" there shall be substituted the words "within twelve hours, if possible, and in any case within forty-eight hours."

PART II: MINOR AMENDMENTS OF THE ACT OF 1947

In subsection (2) of section five (which provides for the treatment, at hospitals providing hospital and specialist services, of the patients of medical practitioners on the staff of such hospitals), after the words "medical practitioner," wherever they occur, the words "or dental practitioner" shall be inserted.

In subsection (2) of section twenty-two (which empowers a local health authority to recover from persons availing themselves of maternity and child welfare services charges in respect of articles provided by the authority) for the words from 'the aforesaid' to "prescribed" there shall be substituted the words "under the aforesaid arrangements there is provided anything that may be prescribed including residential accommodation, food or any other thing" for the words so supplied there shall be substituted the words for whom such provision is made", and for the words of supply "there shall be substituted the words "of such provision"

In subsection (4) of section thirty-two (which empowers the Secretary of State to establish a joint committee for the areas of two or more Executive Councils and to provide, in relation to that committee, for any of the matters for which, in relation to an Executive Council, regulations made under the Sixth Schedule to the Act may provide) for the words "matters for which in relation to an Executive Council regulations made under the Sixth Schedule to this Act may provide" there shall be substituted the words "matters for which, in relation to an Executive Council, provision is or may be made by or under the supplementary provisions of the Sixth Schedule to this Act"

At the end of section thirty-three (which relates to local representative committees) there shall be added the following subsections.

"(3) The Executive Council may, on the request of the Local Medical Committee or the Local Dental Committee or the Local Pharmaceutical Committee for their area allot to that Committee out of the moneys available to the Council for the remuneration of persons of whom that Committee is representative and who provide general medical services, general dental services or, as the case may be, pharmaceutical services under this Part of this Act, such sums for defraying the administrative expenses of the Committee, including travelling and subsistence allowances payable to members of the Committee, as may be determined by the Executive Council with the approval of the Secretary of State, and the amount of any such sums shall be deducted, in such manner as may be so determined with such approval, from the remuneration of the persons aforesaid

(4) Any such Committee as aforesaid may, with the approval of the Secretary of State, delegate any of their functions, with or without restrictions or conditions, to subcommittees composed of members of the Committee"

In subsection (3) of section fifty-four (which provides for defraying out of moneys provided by Parliament payments made in respect of loss of remunerative time or travelling or subsistence expenses to members of any body constituted under the Act) for the words "any loss of remunerative time or any travelling or subsistence expenses" there shall be substituted the words "any loss of earnings or additional expenses (including travelling and subsistence expenses)"

At the end of paragraph (b) of subsection (1) of section sixty-six (which relates to the superannuation of, among others, officers of voluntary organizations providing services under certain enactments) there shall be added the words "or under Part III of the National Assistance Act, 1948"

In paragraph 2 of the First Schedule (which enables the Secretary of State to make regulations for the making of payments to members of the Health Services Council and of standing advisory committees constituted under the Act and of committees and subcommittees set up under that Schedule in respect of loss of remunerative time and travelling and subsistence expenses) for the words "any loss of remunerative time or any travelling or subsistence expenses" there shall be substituted the words "any loss of earnings they would otherwise have made or any additional expenses (including travelling and subsistence expenses) to which they would not otherwise have been subject, being loss or expenses necessarily suffered or incurred by them for the purpose of enabling them to perform duties as members of the Health Services Council or standing advisory committee, or committee or subcommittee set up as aforesaid"

For sub-paragraph (c) of paragraph 2 of Part IV of the Fourth Schedule (which enables the Secretary of State to make regulations for the making of payments to members of Regional Hospital Boards, Medical Education Committees, and Boards of Management in respect of loss of remunerative time or, if special circumstances justify it, in respect of travelling or subsistence expenses) there shall be substituted the following sub-paragraph:

"(c) for the making of payments to members of those bodies or committees in respect of

(i) any loss of earnings they would otherwise have made or any additional expenses (other than expenses on account of travelling or subsistence) to which they would not otherwise have been subject, being loss or expenses necessarily suffered or incurred for the purpose of enabling them to perform any approved duty, or

(ii) any travelling or subsistence expenses necessarily incurred for the purpose of enabling them to perform any approved duty required to be performed at a distance of more than three miles from their usual place of residence"

At the end of the said paragraph 2 there shall be added the following sub-paragraph

"(e) for the payment by a Regional Hospital Board or Board of Management of such sums as may be approved by the Secretary of State, as subscriptions to the fund of any association whose objects are approved by the Secretary of State for the purpose of this sub-paragraph"

At the end of the said Part IV of the Fourth Schedule the following paragraph shall be added

"5 In this Schedule, the expression 'approved duty,' in relation to a member of a body corporate constituted under the foregoing provisions of this Schedule or any committee of that body, means any of the following duties—that is to say

(a) attendance at a meeting of the body or any committee thereof,

(b) the doing of any other thing approved by the body for the purpose of, or in connexion with, the discharge of the functions of the body or any committee thereof,

(c) in the case of a member of the body, attendance as a representative of the body at a conference or meeting convened by one or more such bodies or by any association of such bodies"

Paragraph 1 of the Sixth Schedule (which relates to the constitution of Executive Councils) shall be amended as follows

(a) for the words "a chairman appointed by the Secretary of State and twenty-four other members" there shall be substituted the words "twenty-five members",

(b) in sub-paragraph (b), for the word "four" there shall be substituted the word "five",

(c) at the end of the paragraph, the following words shall be added "The members of an Executive Council shall from time to time, in accordance with such procedure as may be prescribed, appoint one of their members to be chairman of the Council"

After paragraph 3 of the said Sixth Schedule there shall be inserted the following new paragraph

"3A The term of office of the chairman of an Executive Council shall be such as the Council, when making the appointment, determine

Provided that if the chairman ceases to be a member of the Council he shall also cease to be chairman"

For sub-paragraph (c) of paragraph 4 of the said Sixth Schedule (which enables the Secretary of State to make regulations for the making of payments to members of Executive Councils or committees thereof in respect of loss of remunerative time, or, if special circumstances justify it in respect of travelling or subsistence expenses), there shall be substituted the following sub-paragraph

"(c) for the making of payments to members of the Council or any such committee in respect of any loss of earnings they would otherwise have made or any additional expenses (including travelling and subsistence expenses) to which they would not otherwise have been subject, being loss or expenses necessarily suffered or incurred for the purpose of enabling them to perform any approved duty"

In sub-paragraph (e) of the said paragraph 4 the words "and for the payment at the prescribed rates of any expenses reasonably incurred by representatives in attending meetings of any such association" shall be omitted

At the end of the said paragraph 4 the following proviso shall be added

"Provided that

(i) a member of an Executive Council for the area of a local health authority who are the town council of a large borough or a member of a committee appointed by such an Executive Council shall not be entitled to any payments under sub-paragraph (e) of this paragraph in respect of travelling or subsistence expenses in respect of a duty performed within the area of the Executive Council, and

(ii) a member of an Executive Council for any area other than as aforesaid, or a member of a committee appointed by such an Executive Council, shall not be entitled to any payments under the said sub-paragraph (c) in respect of travelling or subsistence expenses in respect of a duty performed within the area of the Executive Council except in respect of duties performed at a distance of more than three miles from his usual place of residence."

At the end of the said Sixth Schedule the following paragraph shall be added:

"8. In this Schedule, the expression 'approved duty,' in relation to a member of an Executive Council or any committee thereof, means any of the following duties—that is to say:

(a) attendance at a meeting of the Council or any committee thereof;

(b) the doing of any other thing approved by the Council for the purpose of, or in connexion with, the discharge of the functions of the Council or any committee thereof;

(c) attendance as a representative of the Council at a conference or meeting convened by one or more Executive Councils or by any association of Executive Councils whose objects are approved by the Secretary of State."

British Medical Association

PROCEEDINGS OF COUNCIL

Wednesday, May 11, 1949

A meeting of the Council was held on May 11. Dr. H. Guy Dain presided, supported by the President (Sir Lionel Whitby), the Chairman of the Representative Body (Dr. E. A. Gregg), and the Treasurer (Mr. A. M. A. Moore).

Obituary

The Chairman referred to the deaths of Dr. J. W. Bone, the late Treasurer, and Dr. W. N. West-Watson, a former member of Council. He recalled the various offices which Dr. Bone had held in the Association, especially his nine years as Treasurer, and the many years over which he had guided the work of the Medico-Political Committee.

It was agreed that the Gold Medal of the Association and the illuminated address which it had been intended to present to Dr. Bone should be presented posthumously to a son, a member of the medical profession, at the Annual Meeting.

Appointment of Delegates

Dr. O. C. Carter was appointed as the delegate of the Association at the forthcoming centenary celebrations of the Netherlands Medical Association, and Mr. R. L. Newell at the centenary celebrations of the Medical Society of the Hospitals of Paris, to be held later in the year.

The Chairman of Council and Dr. J. A. Pridham were appointed delegates to the General Assembly of the World Medical Association, which is to be held in London in October. The Chairman of the Representative Body and Dr. S. Wand were appointed alternate delegates.

Empire Medical Advisory Bureau

Sir Hugh Lett presented the report of the first year's work of the Empire Medical Advisory Bureau. It had been, he said, a year of very satisfactory progress. Contact had been made with very many bodies interested in overseas affairs. The Medical Director (Dr. H. A. Sandiford) had been most assiduous in this respect and had convinced all concerned that the purpose of the Bureau was not to supplant but to supplement the work of other bodies. Especially were they indebted to the British Postgraduate Federation and the Fellowship of Postgraduate Medicine. Some eight or nine "At Homes" had been held in the course of the year, each attended by about 100 overseas visitors and some 50 other people in this country. The Council had been extremely generous to the Bureau, both in the matter of finance and of accommodation, and as a result the prestige of the Association overseas had been distinctly raised.

The President endorsed what Sir Hugh Lett had said. This Empire organization was one of the best things the Council had created.

Popular Health Journal

The Chairman of the Journal Committee (Dr. Carter) brought forward a proposal that the Association should in due time undertake the publication of a monthly popular health journal. A journal of this sort, he said, would be practical public relations of the first order. It would give the profession an opportunity to put over to the public advice on healthy living in a way the individual doctor might have difficulty in doing. He gave certain particulars relating to the technique and costs of production, and acknowledged indebtedness for advice given by experts in the printing and publishing business. It was not expected that the first number would appear until some time in 1950, the date to be determined by the Council at its meeting in March, 1950, in the light of the financial position at that time.

The Council approved the proposal, which is to go to the Representative Meeting. The Council also agreed that the Association should undertake the publication of a monthly periodical for the speedy announcement of research work under the title "Current Research in the Medical Sciences," provided the Publishing Subcommittee, to which the matter was referred, was satisfied that the project was feasible.

Before the Journal report was completed Dr. Pridham expressed the Council's appreciation of the high standard of the *Journal* in recent months as a means of serving the general practitioner. In his view it stood comparison with any other medical journal in the world.

British Medical Guild

Dr. Dain presented to the Council a statement on the local organization of the British Medical Guild—the functions, areas, and constitution of local committees—and the raising of funds. He said that the trustees of the National Insurance Defence Trust had made a grant to form the nucleus of the fund of the Guild. If the proposals set out in the statement were approved for transmission to the Board of Trustees of the Guild the members of Council acting as trustees would be invited to sign the trust deed that day.

Dr. J. B. W. Rowe, referring to a passage in the statement concerning contributions from practitioners outside the three main sections of the profession engaged in the work of the National Health Service, such as non-specialist hospital residents, whole-time industrial medical officers, and general practitioners undertaking only private practice, said that the Guild would function largely as a protection for those in the National Health Service, and he could not see the justification for bringing in practitioners from outside.

Dr. Dain said that the Guild would protect practitioners of all types.

Dr. J. C. Arthur commented on what he called the amorphous relationship of the National Insurance Defence Trust to the Guild. He thought they were still in a position to continue the voluntary levy, but was the levy to be paid to the Guild or to the N.I.D.T.?

Dr. Dain replied that this matter had been discussed with the trustees of the N.I.D.T., and the question of the title was under consideration as well as the question of transfer. Contributions from general practitioners in the Service would continue to be made to the N.I.D.T., under whatever name it might function.

Dr. S. Wand said he was quite satisfied that if there was any confusion at the periphery with regard to the Guild and its purposes it was not due to the statement which had gone out. The role of the Guild was perfectly clear.

The resolution, "That the proposals relating to the British Medical Guild contained in the memorandum be approved for transmission to the Board of Trustees of the Guild," was carried *nem. con.*, two not voting. The trust deed was then signed by members of the Council present, except two, and at a later stage the first meeting of the trustees was held.

Remuneration of General Practitioners

Dr. S. Wand, chairman of the General Medical Services Committee, made a statement on the discussions with the Ministry on general practitioners' remuneration. The discussions, he said, had been unsatisfactory. The Ministry stated that it was not known how many doctors (principals) there were in the Service—this nearly 10 months after the Service started. The

inquiry form which the Ministry had circulated to executive councils was a formidable document, and the Ministry now stated that the figures would not be available within a month, as it had at first predicted. The refusal to give an assurance that any improvement in remuneration would have retrospective effect and the statement that the profession must not rely for a certainty on arbitration in the event of dispute were most disquieting. The refusal of arbitration meant that the profession would be forced into the taking of direct action should negotiations break down. Those who took part in the discussions before July 5, 1948, had no doubt whatever about the understanding that conciliation machinery would be set up, including arbitration, which the profession could invoke if it was dissatisfied.

It had been consistently held out to the profession as one of the advantages of the new arrangement that the issue of remuneration would without doubt come within the field open to arbitration. Those who participated in the earlier discussions had no shadow of doubt on that point, that a permanent conciliation machinery, with arbitration in the background, would be set up.

The report of the Public Health Committee, introduced by Dr. James Fenton, included a recommendation that the Council should take the strongest exception to the Ministry's statement on this point. The whole matter was crystallized in the following resolution, which was carried unanimously:

That the Council deplores the recent statement of the Secretary of the Ministry of Health on the subject of Whitley machinery and arbitration, regarding it as a breach of faith on the Ministry's part because it involves a withdrawal of official assurances and undertakings, repeatedly given to the profession, that the conciliation machinery for the new Service should provide, in the event of disagreement between the parties, for arbitration on questions of remuneration.

In a further resolution the Ministry was reminded of the promise that representatives of the profession would be consulted on the contents of the Amending Bill, and was asked for an early fulfilment of the promise given.

Grading of Specialists

Mr. R. L. Newell, chairman of the Central Consultants and Specialists Committee, said that the committee had held two fully attended meetings, and was to hold another the following day, to discuss the proposed terms and conditions of service. A question of considerable importance concerned the Ministry's proposal for a grade of senior hospital medical officer for senior officers performing general clinical duties, but who were not of specialist status and were not trainees. He thought the Ministry had now been convinced that this grade should be a diminishing one and should be used only as a temporary expedient.

Dr. Wand said it was rumoured that under the Government drive for economy in hospitals certain hospital appointments had been down-graded. Was there any evidence that this had been done on a wholesale scale? Mr. Newell said that there was no such evidence. Grading committees decided entirely on the basis of a man's qualifications.

Mr. Lawrence Abel said that his information was exactly the opposite. Men who had considered themselves consultants or specialists had been down-graded in a large number of cases. In two regions, out of about 100 men who had been doing general surgery, only five had been designated specialists. On the board which decided the grading there was a Ministry representative, whose attitude might well be, "Keep the numbers down as much as possible."

Mr. Dickson Wright said that while there had been no instruction to down-grade there had been an intimation that the hospitals must save £9 million. The Ministry might agree to the profession's terms but keep up its sleeve the number of specialists. Dr. Pridham, Dr. Carter, and Mr. Weldon Watts spoke of disquiet in their areas.

The President said that the unevenness of the grading appeared to constitute the main problem. The discussion would strengthen the hands of the Joint Committee, of which he was chairman, in pressing for a proper means of appeal for the man who thought he had been badly treated. What his committee wanted to know was whether, to the man who had been graded a specialist, the terms and conditions were satis-

factory. The man who had been down-graded would not, of course, find the terms acceptable, but the other point was of extreme importance.

Some discussion took place on the question of filling vacancies on regional boards and the desirability of consultation with the local medical committee when it was a question of replacement of general-practitioner members of the boards, and it was promised that this matter would be looked into at Headquarters.

Occupational Health Service

Dr. J. A. L. Vaughan Jones, chairman of the Occupational Health Committee, presented a report embodying the views of the Association on the question of a comprehensive occupational health service. The report will be published in the Supplementary Report of Council.

The need for an occupational health service, said Dr. Vaughan Jones, had long been recognized by the Association and by other informed opinion. Various Government Departments had developed such services, as had mines, railways, and other industrial undertakings. Many large firms had developed satisfactory services, but such services were most lacking in the smaller factories. The committee was not acting rashly in this matter: the question had been under consideration for the past five years. General practitioners, suitably trained, and acting in a part-time capacity, must be the basis of this service in the future. The bulk of the work would inevitably be done by general practitioners.

No effort was made in the report now placed before the Council to enter upon detailed plans, but it was felt that the central authority responsible for the planning of the occupational health service should be the Ministry of Health, and that a survey of the whole country should be made in relation to need. Such a survey would involve considerable outlay, and various suggestions had been made—one that the Nuffield Foundation might assist. But it was fundamental, before going any further in relation to such a service, that a survey be made in which due regard would be paid to the question of available medical man-power and to the extent of the demand in different areas for such a service.

Dr. Frank Gray said he entirely agreed with the conclusion stated in the memorandum that the Ministry of Health was the appropriate central authority to plan and supervise a national occupational health service, but the most important argument for this proposal seemed to have been omitted. Occupational health was, after all, a sort of fiction. Health services dealt with people; it was not possible to separate the man at work from the man at home, and whatever affected his health would affect him both when he was at work and when he was at home. He wanted to see that argument accepted and stated. Also, in para. 12 of the document, he thought the words should be "the Government Department" (as the supervising body)—not "a Government Department."

The Council unanimously agreed to recommend the report to the Representative Body.

The chairman of the Occupational Health Committee explained that recent discussions with the National Dock Labour Board had removed certain misunderstandings that had arisen as to the work which the Board had authorized its medical officers to carry out at Avonmouth Docks. The committee, while still opposed in principle to work of this kind being performed by public-health medical officers in receipt of full-time salaries, was now satisfied that no exception could be taken to the policy of the Board in regard to the scope of the duties undertaken by its medical officers. In these circumstances the Council, on the recommendation of the committee, decided that advertisements of medical appointments under the Board should be accepted if offered for publication in the *British Medical Journal*.

Loan to Medical Association of Eire

The Treasurer stated that an application had been received for a loan to assist the Medical Association of Eire to establish an Association House in Dublin. The house which the association was endeavouring to obtain was in the neighbourhood of Merrion Square, and was of a design which lent itself for easy conversion into offices. The Finance Committee, said Mr. Moore, recognized that as a corporate body analogous to

an organized Branch of the Association the Medical Association of Eire should be given all possible help to obtain accommodation in keeping with the dignity of the profession and of the two Associations, and accordingly recommended that a loan of £10,000 for the purchase of the house on a long-term lease should be made without interest. The redemption of the loan within a stated period would be guaranteed by a sinking-fund policy.

The Finance Committee's recommendation was agreed to unanimously.

Medical Ethics

Dr. J. G. Thwaites, for the Central Ethical Committee, brought forward a memorandum on "Ethics and Members of the Medical Profession," with a suggestion that it be distributed to those who had qualified within the last ten years.

Dr. Pridham suggested that the "Declaration of Geneva," which the World Medical Association wanted every doctor to accept on qualification, should be incorporated in the document. The World Medical Association had elaborated a code of ethics for acceptance by all national medical associations.

The document was unanimously approved.

Organization

For the Organization Committee Dr. Pridham presented a report on the conduct of business at Representative Meetings. It contained suggestions for possible methods of dealing with the problem of congested agenda, but no recommendations. He said that the report would be presented to the Representative Body, which would decide for itself on the method to be adopted. It was agreed to include in the report a note on the manner in which other large public assemblies dealt with the same problem.

The Council set up a special committee to consider and report upon the constitutional position of Branches of the Association overseas, other than corporate Branches, with special reference to the question of affiliation of the Association with the Indian Medical Association.

Dr. Pridham called attention to a memorandum on the role of Divisions in the medico-political work of the Association, which he hoped would be published in the *Journal*. He reported that the Association membership was now at its highest peak—60,441.

The Council authorized its Chairman to forward a suitable letter to 13 honorary secretaries of Divisions and Branches who have recently relinquished office.

Association of General Practitioners with Hospital Work

A report was made by the Joint Committee on Association of General Practitioners with Hospital Work. One of its recommendations was that certain hospital wards in or attached to general hospitals, to be used in association with the specialist staff of a hospital, should be made available to general practitioners. Dr. G. MacFeat considered this to be a very "milk-and-water" recommendation and urged, on the lines of an earlier proposal, that a general-practitioner hospital or wards in a general hospital should be provided in suitable areas at the request of the local practitioners where all doctors in the area might treat their in-patients. He considered that there was now an opportunity of doing something of real value in connexion with general-practitioner hospitals.

Dr. Wand, a member of the Joint Committee, said that the recommendation now brought forward was likely to be the first of a number, and as there was no special urgency he was willing to take it back to the committee, together with the more definite proposals put forward by Dr. MacFeat. The same procedure was followed in connexion with another recommendation concerning general-practitioner specialists.

Other Committee Reports

On the report of the Scottish Committee Dr. MacFeat said that the committee was collecting by means of a questionnaire sent to all practitioners in Scotland in receipt of mileage payments particulars of actual mileage travelled, special mileage, car expenditure, and other details, and the replies would be considered by a special subcommittee.

Recommendations by the Armed Forces Committee protesting against the existing discrimination against National Service

officers in the armed Forces in matters of marriage allowance and leave entitlement (which it was said reacted particularly harshly upon medical officers, many of whom, owing to the late age of call-up, were married before entry to the Forces) were agreed to by the Council.

Dr. Mary Esslement said that the Committee on Nursing had examined the Nurses Bill and would endeavour to arrange for certain amendments in accordance with views previously approved by the Council.

Certain paragraphs dealing with health centres in rural areas were approved for inclusion in the Council's final report on health centres.

The terms of reference of the International Relations Committee—"to foster international friendship in the sphere of medicine and to make recommendations to that end"—were agreed; also that the committee should report to the Council in April of each year proposals for international receptions.

For the Colonies and Dependencies Committee it was reported that the memorandum already approved on the remuneration of officers in the Colonial Medical Service had been submitted to the Colonial Office, which had agreed to open negotiations as soon as certain preliminary investigations had been completed.

Reports dealing with routine and domestic matters were submitted by the Staffing, Office, Public Relations, and Building Committees and were approved.

Annual Meeting, 1950

An invitation from the Executive Committee of the Liverpool Division to hold the Annual Meeting of the Association in 1950 in Liverpool was received. It was stated that the Southport Division desired to be associated with the invitation, which should be regarded as a combined one from both Divisions. The Council gratefully accepted the invitation and endorsed the Liverpool nomination for President of Professor T. P. McMurray, of the University of Liverpool, for recommendation to the Representative Body.

The British Medical Guild

Dr. H. Guy Dain was appointed Chairman of the Trustees, and Dr. Frank Gray Treasurer. A committee of 12—members of the Trust—was set up with power to act, within the framework of the document just approved, to initiate peripheral machinery and undertake other detailed work.

Branch and Division Meetings to be Held

BLACKPOOL AND FYLDE DIVISION.—At Royal Lytham and St. Annes Golf Club, Tuesday, May 24, Treasurer's Cup Golf Competition.

EAST SUFFOLK DIVISION.—Friday, May 27, 8.15 p.m., lecture by Mr. Lionel Cosin: "Geriatric Care."

MONMOUTHSHIRE DIVISION.—At Newport Golf Club, Rogerstone, Sunday, May 22, Spring meeting of Newport and Monmouthshire Medical Golfing Association.

NORWICH DIVISION.—At Museum, Norfolk and Norwich Hospital, Friday, May 27, 8.30 p.m., annual meeting. Instruction of Representatives to Annual Representative Meeting, etc.

OXFORD DIVISION.—At Lecture Room, Radcliffe Infirmary Maternity Home, Wednesday, May 25, 8.15 p.m. Mr. N. S. Barron, Ph.D.: "Some Diseases of Animals Communicable to Man."

SCARBOROUGH DIVISION.—At Scarborough Hospital, Thursday, May 26, 8.30 p.m., clinical meeting. Dr. Hugh Garland: "The Intervertebral Disk."

SHEFFIELD DIVISION.—At Royal Victoria Station Hotel, Friday, May 27, 8.30 p.m., annual general meeting.

JENNER AND HIS IMPACT ON MEDICAL SCIENCE

BY

Sir EDWARD MELLANBY, G.B.E., K.C.B., F.R.C.P., F.R.S.

We are assembled here to-day to celebrate the life and work of Edward Jenner, who was born in Gloucester 200 years ago on May 17, 1749. We come to pay tribute to a man who discovered that vaccination protected against smallpox, and thereby placed in the hands of any community which cared to make proper use of it the means of eliminating from their midst a deadly and disfiguring disease. The method was effective as Jenner presented it, and all the new knowledge and technical skill that have been added in the last 150 years have not changed its fundamental basis or added much to its efficiency.

Apart from the value of vaccination in controlling or even eliminating smallpox, this discovery of Jenner's has much wider significance. It was one of the earliest instances of preventive medicine and of the public control of disease. Its value on the scientific side of medicine is just as imposing, for Jennerian vaccination can be regarded as the parent of modern work on viruses and virus diseases and even of modern immunology. Indeed, it would be difficult to mention any discovery that has had a greater impact both on public health and on medical science, and it is but right that we should pay tribute to the man who was responsible for this important advance in knowledge.

So much emphasis is nowadays placed on technique and statistical approval of investigations that it is well for us to take this opportunity of reminding ourselves that the first object of research is discovery, and that such discoveries may come not only from systematic and prolonged investigation, involving the use of standard methods with elaborate apparatus, but equally well from methods of observation and experiment of the simplest kind. Jenner himself was no professional research worker but a man with exceptional powers of observation and perception, who had also the outstanding quality, remarkable for this period and apparently innately developed, of appreciating the value of the experimental method.

There is a vast amount of information about Jenner's life. Indeed, it would be difficult to find anybody of that period whose actions, experiences, and thoughts were better documented, and it would have been easier to centre this lecture round his history. I do not propose to do this, however, because I am anxious to paint a broader picture of his work and its influence on medical science. It would, however, be wrong to eliminate all such references, because, clearly, a proper appraisal of his work must depend in part on the state of knowledge at that time and on the conditions under which he was brought up and laboured. There has been a tendency to write about and discuss Jenner as if he had the knowledge, outlook, and facilities of later days. I wish therefore to refer briefly to some of his experiences, specially during the formative years of his life, in order to convey an idea of his training, his equipment, and the circumstances in which he made his observations.

A Brief History

Edward Jenner was the son of a country parson living in Gloucestershire, and at the age of 13 was apprenticed to a doctor with the intention of becoming an apothecary. Under Ludlow, a surgeon at Sodbury, near Bristol, he studied pharmacy and surgery. In 1769, at the age of 20, he had the good fortune to become an apprentice to John Hunter, then a surgeon at St. George's Hospital and the owner of a menagerie at Brompton, where he made his world-famous studies on the structure and habits of animals. Hunter was then 41. Hunter and Jenner dated their intimate friendship from this time and began a correspondence which only ended with Hunter's death in 1793. Hunter expected much from his assistants, but he was equally good in giving them help and opportunities for advancement. Thus, in 1771, when Captain Cook returned from his voyage to the great southern continent with a large cargo of natural history specimens, mostly collected at Botany Bay, it fell to Jenner's lot, through the influence of Hunter and of Sir Joseph Banks, then President of the Royal Society, to prepare and arrange these specimens. This he did with such skill that he was offered the appointment of naturalist to Captain Cook's next expedition, which sailed in 1772.

Other evidence of Jenner's capability is seen in the fact that Hunter also suggested that he might become his partner and give additional lectures on comparative anatomy and surgery. Both these invitations were rejected, however, and Jenner preferred to return to his native village to become a country doctor in the vales of Berkeley and Gloucester.

Throughout his life one of Jenner's main interests was natural history, and it was in 1787 that he sent his manuscript on the behaviour of young cuckoos through Hunter to the Royal Society. In this publication, it will be remembered, he showed that fledgling cuckoos heaved out of the unnatural nest in which they were born other fledglings and eggs, a murderous instinct they lost by the twelfth day after hatching. It was not only Fellows of the Royal Society who found difficulty in believing this observation, and its complete acceptance had indeed to await the arrival of the cinematograph. However, a year later, in 1788, the work was published by the Royal Society in its *Philosophical Transactions*, and Jenner was elected to the Fellowship of the Society.

While a medical student at Sodbury, Jenner heard the local traditional rumour that milkmaids who had suffered from cowpox never took smallpox. There is much evidence that he was not only intensely interested in this statement but that he brooded on it and studied the matter closely during the next twenty years. In 1796 he made the first vaccination—that of a boy—with lymph made from the vesicle on the hand of a milkmaid infected with cowpox. In 1797, when he was 47, he sent to the Royal Society for publication a record of his observations on the natural history of cowpox, and this was rejected. It is said that the refusal to publish this work was accompanied

*Lecture given at the bicentenary meeting held at the Royal College of Surgeons of England on May 17.

by an admonition that "as he had gained some reputation by his former papers to the Royal Society, it was not advisable to publish this one, which would injure his established reputation." The paper, revised and extended, was published by Jenner in 1798 as a private pamphlet with the title *An Inquiry into the Causes and Effects of the Variolae Vaccinae, a Disease discovered in some of the western counties of England, particularly Gloucestershire, and known by the name of the Cow Pox.*

Jenner lived in Gloucestershire as a busy country practitioner all his life, except for a short period in 1802, when he was tempted by the importunity and promises of his friends to become a specialist in London. This was a failure, financial and otherwise, and caused a return to his own countryside after three months. It must be added that Jenner did not retain the status of an apothecary, but in 1792 took the M.D. degree of St. Andrews University and did some consulting work in Cheltenham. From the time he published his paper on smallpox in 1798 Jenner, although living a secluded life in the country, was a notorious public figure, much applauded and much criticized. He spent most of the rest of his life vaccinating people and promoting vaccination as a preventive of smallpox. He died at the age of 74.

His Association with Hunter

This, then, is a brief outline of his career. It would be wrong, however, to pass without further discussion Jenner's interest in natural history and especially his relationship to Hunter. There might appear at first sight to be nothing exceptional about Jenner's interest in nature at that time, for, as is well known, there was a tremendous outburst of activity in this field dating from the middle of the eighteenth century and probably stimulated largely by the systematization of animals and plants by Linnaeus. The literature of that period is full of works, often of a very high standard, on natural history. Most of this, however, was of an observational type, and investigations were largely directed to the classification and description of the natural life of the country, including the birds, butterflies, and flowers. But Jenner's interest in natural history was due neither to the fashion of the times nor to Hunter, for at the age of 9 he had made a collection of dormouse nests and one of fossils from the oölite.

In the long correspondence with Hunter, of which only Hunter's letters are extant, it is possible to see not only the close personal relation between these two men but also how they reacted on one another and constantly stimulated each other to further action. Most of Hunter's letters are full of requests for animals and birds of one sort or another. He asks Jenner to send him young blackbirds of different ages, crows' and magpies' nests, an old cuckoo and a nest with a cuckoo's egg in it, a live heron or bittern ("see how they make the noise!"), a porpoise, white hares (a buck and a doe) from Jenner's friends in Newfoundland, bats from the old castle at Berkeley, and fossils, more hedgehogs—"a colony of them"—and even a bustard. Besides asking for these things, he was constantly telling Jenner to do things, to send him "a true and particular account of the cuckoo and, as far as possible, under your own eye," to take temperatures of hibernating animals; and, above all, as is well known, it was in this correspondence that he told Jenner not to think but to try the experiment.

Hunter's letter of June 7, 1773 or 1774

"I thank you for your experiment on the hedgehog; but why do you ask a question by the way of solving it? I think so just; but why think? Why not try the experiment upon a hedgehog as I am, the Nat give you the solution and I hole."

There were, however, some more human touches about these letters of Hunter's: for instance, when Jenner announced that he had had a severe disappointment in marriage Hunter wrote to him: "I own I was glad when I heard that you was married to a woman of fortune but let her go; never mind. I shall employ you with hedgehogs, for I do not know how far I may trust mine."

On another occasion Jenner asked Hunter to be godfather to his child. Hunter replied, accepting the office as follows: "I wish you joy; it never rains but it pours. Sooner than the brat should not be a Christian I will stand Godfather for I should be unhappy if the poor little thing should go to the Devil because I would not stand Godfather. I hope Mrs. Jenner is well and that you begin to look grave now you are a father." On the whole, however, these letters are very much to the point and concerned almost entirely with either ordering or acknowledging the receipt of natural history specimens or criticizing Jenner's experiments.

One of Jenner's great characteristics was that he seemed to make use of every opportunity that was offered to him. For instance when he met Hunter in Bath on one occasion he saw at once that Hunter was suffering from angina pectoris, which was the ultimate cause of his death. The ordinary man would have been greatly perturbed at seeing this condition in a friend but would have done nothing about it. Jenner, however, did not take this line, but wrote to Heberden, who was in medical charge of Hunter, about his diagnosis, and, moreover, began to take an interest in the condition of the heart which was associated with this disease.

The result was that he made the first observation on the thickening and calcification of the coronary arteries in this disease, and, although out of a natural reticence he did not pass on this information to Hunter, he told Home, Hunter's brother-in-law, of the fact. After the post-mortem examination on Hunter, Home wrote to Jenner in the following words: "It is singular that the circumstance you mentioned to me and were always afraid to touch upon with Mr. Hunter should have been a particular part of his complaint, as the coronary arteries of the heart were considerably ossified." When we remember the long period of time that elapsed before it was generally accepted that the pathological basis of angina pectoris was coronary disease, it is remarkable that this observation should have been made by Jenner at that time.

Although the records of Jenner's observations on natural history which he wrote in his notebook between 1787 and 1806 are meagre, from them it can be seen at once that he was no mere collector or casual observer of nature but a man who observed accurately and persistently and had the faculty of picking out the essential from the dross. His post-mortem records of the egg-forming organs of birds and of the abnormalities to be observed in dogs which had died of distemper show these qualities. Nor did he hesitate to put his ideas to the test, as, for instance, when he exchanged eggs and fledglings from one nest to another or when he marked birds before migration and observed the results. Where Jenner made simple observations or experiments his recorded results can be regarded as correct. When he had preconceived ideas on subjects about which there was little or no knowledge, he made mistakes in deduction, as, for instance, when he decided that tubercles in the lungs were derived from hydatids.

The general impression to be derived from these notes is that Jenner had the mental outlook and qualities of a genuine discoverer, and that it is no mere chance that he did in fact make discoveries.

Discovery of Vaccination

Probably one of the simplest ways of focusing attention on Jenner's great discovery of vaccination against smallpox, and especially upon its basis, would be to recall the criticism that has often been brought against him for having given the name *variola vaccinae* to cowpox. Even the fact that he put this into Latin has caused criticism. The further charge was that, by giving such a name, he insinuated into the minds of medical men that cowpox was smallpox. He was accused of having introduced "an unblushing invention of a misleading name," that he was "wanting in the rudiments of common candour," that this was an action of sheer trickery, and that the profession were thereby mystified and hoodwinked about the true nature of cowpox. Had it turned out that the facts upon which Jenner had given this name were incorrect, these critical scholars would certainly have had some cause for rejoicing, but, as we all now know, Jenner was right on almost every practical and scientific point.

Let us first see what he himself thought on this matter when he introduced the words *variola vaccinae*. He wrote: "There are certainly more forms than one (without considering the common variation between the confluent and distinct) in which the smallpox appears in what is called the natural way. It will be inquired (if the foregoing reason be *a priori* correct) in what way can the action of cowpox (or the equine pock) in preventing subsequent smallpox be reconciled with the established laws of the animal economy? My reply is, for the reasons which I have stated on the basis of fact, that they were not *bona fide* dissimilar in their nature but, on the contrary, identical. On this ground I gave my first book the title of 'An Inquiry into Causes and Effects of the *Variolae Vaccinae*,' a circumstance which has since been regarded by many as the happy foresight of a connexion which was destined by future evidence to become warranted."

Let us now see what modern scientific evidence has proved and what posterity has had to say about this claim of Jenner's, which in reality was the essential basis of his discovery of vaccination for smallpox. In 1902 Copeman inoculated a monkey with smallpox virus, vaccinated a calf from the monkey, and produced typical cowpox. Later Blaxall found that both *alastrim* (*variola minor*) and *variola major* viruses from human subjects produced a papulovesicular lesion on the skin of a monkey but not on the skins of calves or rabbits. Either of these two *variola* viruses protected the monkey against *vaccinia* and, conversely, *vaccinia* protected it against both of them. He then succeeded in increasing the virulence of both forms of *variola* virus for the calf, so that in the space of three successive passages the calf developed the typical lesions of cowpox.

Thus it was demonstrated that the biological difference which specimens of *alastrim* and *variola* viruses exhibited when removed from man disappeared when they were passed through the calf. As a control virus Blaxall used material from *varicella* (chicken-pox), which he found, as previous observers had done, to be without effect on the skin of the monkey or other animals. Similarly, by employing the specific test of allergy introduced by von Pirquet, he showed that the viruses of *vaccinia*, *variola*, and *alastrim* behaved alike but were sharply differentiated from the virus of *varicella*.

Later Gordon showed that *vaccinia* protected the monkey against other strains of mild and severe types of smallpox better than these strains of *variola* protected the animal against *vaccinia*. He further showed that the *variola* virus from five outbreaks, including three of the mild and two of the severe types of smallpox, reacted positively

with *antivaccinia* serum in the complement-fixation and agglutination tests.

The Father of Modern Virus Studies

In a lecture of this kind it is possible to refer to only a trivial amount of evidence on this question, but Jenner would indeed derive much fun and satisfaction from the mass of investigation on *vaccinia* and *variola* viruses if he could visit us to-day. He would see the unassailable evidence of the truth of his observations on man in 1798 that *vaccinia* protected against *variola*. He would find that we now know more about the morphology and the biological properties of *vaccinia* virus than of any other virus. He would greatly appreciate modern methods of altering the type of lesions produced by *vaccinia* virus and of selecting different strains of virus which, although antigenically and immunologically indistinguishable, can cause under appropriate conditions cutaneous lesions, meningo-encephalitis, orchitis, pneumonia, or keratitis—i.e., degrees of difference in biological action of one virus greater than those of the smallpox and cowpox virus with which he was familiar.

He would be greatly interested to learn that, in spite of all these different biological properties that can be induced in *vaccinia* virus and in spite of the remarkable cross-immunization properties and the closely related antigenic and immunological actions of *variola* and *vaccinia*, it is widely believed that *variola* and *vaccinia* viruses are different entities, and that the evidence that one is ever completely transformed to the other is insecure.

At this stage of my reading about pox viruses I also began to feel insecure, and decided to call in an expert bacteriologist for the latest stop-press views about the interrelation. He provided me with the following statement: "It has been generally assumed, since the days of Jenner, that *vaccinia* is *variola* modified by passage through the calf. For this there is good evidence, supported by modern experimental work. The further assumption, however, that *vaccinia* is the same disease as naturally occurring cowpox virus is more doubtful, since Downie has shown that *vaccinia* and cowpox viruses differ in their heat-labile antigens and give rise to different lesions in animals. Both viruses can, of course, protect against *variola*. Thus *vaccinia* virus is almost certainly a derivation of human smallpox virus, but cowpox virus is a naturally occurring and rather different virus belonging to a much larger group of animal pox viruses."

Jenner would be amazed to learn of the present enormous field of knowledge of other virus diseases and of the information that has been accumulated about the properties of these viruses. He might just be a little uneasy about some of the new knowledge. For instance, he might think that, from the scientific angle, it was fortunate his particular problem concerned smallpox and cowpox and not the influenza viruses A and B, which, while producing similar morbid effects in man, do not protect against each other. He would realize that he probably would not have made much headway in preventing distemper in dogs—a disease which did interest him intensely—on learning that when the virus of this disease is transmitted to ferrets the infected material from the ferret will not protect against distemper in the dog nearly so well as the dog's virus itself, in spite of the fact that the infective agent is the same in each case.

However, Jenner in fact did choose smallpox as his objective, and, in spite of the complexity of virus problems which now face the scientific world, some due to their innate properties and some to the various species of animals and the different tissues in which their biological reactions have been studied, he would have the supreme satisfaction of realizing that he started all this work, that his views on

the relationship of smallpox and vaccinia have been generally confirmed, and that indeed he can well be regarded as the father of modern virus studies and of the biological and pathological reactions they produce.

Official Approval

So far as the subsequent history of vaccination is concerned, I shall simply recall that Jenner's triumph was great when the National Vaccine Board, consisting of the President and four Censors of the Royal College of Physicians and the Master and two Governors of the Royal College of Surgeons, was set up in 1808 by the Government. The immediate stimulus to this action was the report of the Royal College of Physicians, published in 1807, which concluded with the following words:

"The College of Physicians feel it their duty to strongly recommend the practice of vaccination. They have been led to this conclusion by no preconceived opinion, but by the most unbiased judgment, formed from an irresistible weight of evidence which has been laid before them. For when the number, the respectability, the disinterestedness and the extensive experience of its advocates are compared with the feeble and imperfect testimonies of its few opposers; and when it is considered that many, who were once adverse to vaccination have been convinced by further trials, and are now to be ranked among its warmest supporters, the truth seems to be established as firmly as the nature of such a question admits; so that the College of Physicians conceive that the public may reasonably look forward with some degree of hope to the time when all opposition shall cease, and the general concurrence of mankind shall at length be able to put an end to the ravages at least, if not to the existence, of the smallpox."

In the light of this edict it is strange that variolation—namely, the inoculation of smallpox material as a prophylactic against the disease—which had been practised in the East from time immemorial and introduced into England largely owing to the influence of Lady Mary Wortley Montagu about 1722, continued to be practised in England until it was made a penal offence by the Vaccination Act of 1840. The long continuation of inoculation for smallpox for a period of over 30 years after the official acceptance of vaccination is an example of official inertia, especially in view of the truth and force of Jenner's arguments that it was a more dangerous procedure to the individual than vaccination, and that it allowed the continuation of smallpox itself throughout the community. However, in most ways vaccination had a rapid and world-wide acceptance.

Influence of Jenner's Discoveries

When we turn to the wider question of the influence of Jenner's discoveries on epidemiological and scientific advance of knowledge we find a different and more depressing picture which, because of its ultimate great triumph, makes us realize more fully how long before its time, from a scientific angle, Jenner's discovery was made. For 80 years, apart from smallpox itself, Jenner's work was without influence in the wider field of protection against infective and infectious disease. In 1877, however, the scene was changed, for it was in that year that Pasteur, whose reputation was already very high because of his work on fermentation and infection of plant life, turned his attention to human and animal disease.

There is no doubt that when he began to investigate anthrax and other diseases he studied closely the literature of immunity to smallpox following variolation and Jenner vaccination and that it was Jenner's work which primarily caused him to think that a similar state of affairs might hold for other diseases; the first malady he studied from this angle was chicken cholera. It will be remembered that in 1881 he gave an address in London at the International Medical Congress on vaccination in relation to chicken cholera and splenic fever. It

was on this occasion that he explained his adoption of the words "vaccine" and "vaccination" to denote the process of prophylactic inoculation in general and expressed his indebtedness to Jenner's work in the following words:

"I cannot complete this address, however, without testifying the great pleasure I feel that it is as a member of an international medical congress meeting in England that I finally communicate to you the vaccination of a disease probably more terrible for domestic animals than smallpox for man. I have given to the term vaccination an extension which science, I hope, will consecrate as a homage to the merit of and to the immense services rendered by one of the greatest of Englishmen, your Jenner. I am indeed happy to be able to praise this immortal name in the noble and hospitable city of London."

It may not be without interest to mention that the president of this congress, the late Sir James Paget, in thanking Pasteur for his address, pointed out that what Jenner had done for the good of the human race Pasteur had done for the good of animals, but, whereas Jenner had had to fight his battle for the benefit of men's lives against a vehement opposition, Pasteur had met with no such opposition in his work for the benefit of cattle. We still meet with this kind of relative reaction—an indication that human nature has not changed very much in the last 150 years.

Pasteur follows Jenner

In developing a treatment for fowl cholera Pasteur followed Jenner in first producing enfeeblement of the virus, which he called attenuation. As in the case of smallpox he noticed that if fowls recovered from the effects of inoculation of the virus the disease was not likely to recur, and that if relapses did occur they were in inverse ratio to the severity of the first attack. If the virus was transplanted from medium to medium at intervals varying from days to a month or two, no change was observed in the virulence for fowls. If, however, the interval was prolonged to three, four, or five months the cultures became less and less virulent and the fowls, even if they fell ill, recovered and if they were now injected with a virulent cholera culture they survived the injection. By this means he discovered prophylaxis of fowl cholera by attenuated virus, a principle which he also established for anthrax, swine erysipelas, and rabies.

In the case of anthrax he noticed that domestic animals occasionally recovered from the disease, which suggested that they developed natural immunity. He observed that the anthrax bacillus did not grow at 45° C. but grew well at 42-43° C. At the latter temperature, however, the culture became asporogenous and died out altogether in a month. When a virulent anthrax culture was kept at a temperature of 42-43° C. for eight days it was found to have lost much of its potency and was innocuous when injected into guinea-pigs, rabbits, and sheep.

Pasteur then proceeded to give a public demonstration of this work on 24 sheep, 6 cows, and 1 goat. On May 5, 1881, these animals were each inoculated with a living attenuated culture of anthrax bacilli. On May 17 the animals were reinoculated with a less-attenuated culture. On May 31 all 31 animals received a highly virulent anthrax culture, which was also inoculated into 24 sheep, 1 goat, and 4 cows not previously inoculated and serving as controls. On June 2 all the vaccinated animals were well, 21 of the control sheep and the goat were dead from anthrax, 2 of the control sheep dying in the presence of the spectators, which included a correspondent of *The Times*. The result of this test created an enormous sensation, and from this time immunology may be regarded as having been established. Pasteur himself said of this work that it was "un progrès sensible sur le vaccin Jennerien."

In this final phase of his work Pasteur, although a cripple, following a cerebral haemorrhage, but mentally as alert

ever, turned his attention to rabies. Making use of the fact discovered by Galtier in 1881 that rabies was transmissible to rabbits, he first showed with Chamberland and thus that the virus of rabies entered the central nervous system. His next key observation was that spontaneous recovery very occasionally happened in dogs, and in five such dogs he found that subsequent intracerebral inoculations were without effect. Here again he had a disease with an immunity factor and with a virus transmissible to animals and therefore with a basic similarity to smallpox and anthrax. Clearly the principle of attenuation of the virus was presented.

As is well known, he proceeded on the one hand to exalt the activity of the virus by passage through rabbits, and on the other hand to attenuate its activity by suspending infected spinal cords in dry, sterile, and still air. After inoculation of emulsions of the attenuated cord he found it possible to inject emulsions of less-attenuated cord, and finally emulsions of the most powerfully active virus, with impunity. In 1885 he extended these observations to human beings, when he treated a boy aged 9 who was brought to him suffering from extensive bites inflicted by a dog with rabies. The boy was first injected with attenuated rabbit spinal cord which had been kept for 14 days. In a further series of 12 injections he received virus that was stronger and stronger until he was injected with the most virulent spinal cord, which had been taken from the rabbit after one day only. This boy remained well. That was the beginning of the modern method of treating this disease.

I have given this brief summary of Pasteur's work on the production of immunity on the basis of attenuation of virus because it seems to me that Pasteur's public recognition of Jenner's influence on his great work should be widely recognized. The same basic principles underlying Pasteur's remarkable discoveries are obviously present in Jenner's work on vaccination and smallpox. In all the diseases studied by Pasteur, as in Jenner's discovery, there was evidence of the invasion of the animal body by a virus (using the word in its older sense), and of the animal's power to build up a natural resistance to the disease, and the problem in each case was to find or produce a virus in an attenuated form which on injection promoted immunity to the fully virulent agent. The subsequent development of the whole subject of immunology since Pasteur's day has of course been enormous, not only in what are now known as virus diseases but also in diseases due to other types of pathogenic micro-organisms. Should we therefore be far wrong if we extended the suggestion previously made that Jenner was the father of modern work on virus disease to the proposition that he might also well be regarded as the father of the whole domain of immunology?

Unjust Criticism

So far I have refrained from discussing the personal qualities of Jenner, except to say that his mental characteristics were clearly those of a potential discoverer; I have been content to deal with his experiences, his work and its results, and allowed them to speak for themselves. It is impossible, however, to read the extensive literature about Jenner without finding that he has been subject to more than his share of criticism and even of defamation, in regard to both his work and his character. This criticism has come not only from ignorant people with strong views about vaccination but also from some who would be regarded as scholars of medicine. In other words, into this literature scholasticism has entered.

We have been fortunate in medical science in having had only a minimum of the kind of writing which was such a prominent feature in theological studies of the Middle

Ages. One of Jenner's critics who has been described by Greenwood as "an exact scholar and a highly educated man" and by W. Bullock as "a scholar and philosopher—the most learned man I ever knew," in the course of what has been described as an exposure of Jenner wrote about him as follows: "They would probably have found Jenner to be the vain, imaginative, loose-thinking person that he certainly was by nature, and they might have so acted as to prevent him from becoming the impostor and shuffler that the course of events made him."

If this accusation stood alone it might well be disregarded, but I find that my friend Greenwood fully accepts the statement as regards Jenner being "vain, imaginative, and loose-thinking," though he suggests that the words "impostor and shuffler" in the second part of the sentence might be replaced by the description "fact-blinded enthusiast." In my view these judgments are not only unbalanced but wrong, and could have been made only by those who have little knowledge of and make but little allowance for human nature. We all know instances of writers of this type, and I want to take this opportunity of saying that it will be a sad day for medical science if such writing becomes a prominent feature, for there is but little room in scientific work for this sort of scholasticism. "Killing Kruger with your mouth" is at any time a poor game and in scientific work has no place. This was well recognized by the Royal Society when they adopted the motto "Nullius in Verba."

If a man thinks that the facts described by an investigator are wrong, then it is no good simply writing about them. The critic must go into the hospital or laboratory and make better observations or better experiments in order to prove his contention. The test of the acceptability of a discovery depends upon whether it is true and not whether it seems sensible or even whether it can be verified by the statistician. Most of Jenner's deductions from his work proved to be true. A few of his observations, such as, for instance, that a condition called "grease," a disease of the heels of horses, is the initial source of cowpox, have, I believe, proved to be untrue (although he was right in believing that there is a pox disease of horses), and occasionally his deductions, especially those concerning the infallibility of the protecting influence of vaccination against smallpox, were exaggerated, but this kind of defect will be found in the works of most scientific investigators, and the more fundamental their discoveries in medicine and biology the more likely are they to make mistakes at some time or other.

Speaking on the basis of my own experience in medical research, it seems to me that most facts published by scientific men are true but that they are apt to make two types of error, especially in the early accounts of their work. The first is that they sometimes forget that their results are true only for the conditions under which they are working, and the second is that they are apt to make unwarranted deductions regarding the implications of their results. In the latter case these often prove to be wrong. As regards the first source of error, it is clearly the object of the critic, if he once finds that the first man's results no longer hold, to search out the conditions which may have modified the earlier results. This is the normal method of procedure in research, and nearly always leads to new knowledge.

If, on the other hand, a man is to be condemned and denigrated because the implications of some discovery prove to be unsound, then I can only say that very few scientific men, even of the finest type, will have a shred of reputation left when they have been handsomely dealt with by our scholars. No part of a man's work in biological and medical science is more difficult than that of foreseeing the implications of a new fact which opens up a new

branch of knowledge, for, unlike research in the physical sciences, it is often impossible to realize the complexity of the conditions or to prejudge the relative importance of the factors concerned.

When the critic goes further and extends his criticism from the man's experimental work to his character and to his motives the position becomes intolerable, and it is this feature of the criticisms of Jenner which induced me to make this protest. I have read a good deal about the life and the work of Jenner in the last few days, and I find that the judgments of the above-mentioned scholars on this man are just incredible. My views about Jenner as an investigator can be seen from what I have said, and I think I should add that my judgment about his character is that he was a fine type of man. The whole of his life's history seems to me to point to this: his desire to avoid the scurry and publicity of life, his kindness to his family and relations, the time and trouble he took over his patients, his readiness to participate in the local life of his village community, his interest and participation in the arts, including poetry and music, his social relations with his fellow doctors, as judged by the local medical societies he formed—all indicate a man who both appreciated the best things in life and wished to help to the utmost his fellow-man. Independently of any of his discoveries and their results, he could be regarded as the best type of country doctor.

Outstanding and Successful Pioneer

It is, however, the man in relation to his discoveries whom we celebrate to-day, and I have tried to picture one who was bound to make discoveries wherever he was placed and who deliberately chose the circumstances where in fact he made the greatest of discoveries. This not only gave direct control of one of the most devastating of diseases but it also formed the basis of all modern work on immunology and of the fruitful field of virus disease.

Apart from Jenner's distinction, may I add how proper it seems to me that the Royal College of Surgeons and the Royal College of Physicians should participate in this celebration to-day, even if it serves only as a counterblast to the constant reiteration of public men in Parliament, in the Press, and on the radio that scientific research has as its main object the discovery of weapons and machinery for the destruction of man. All public attention seems to be given nowadays to this point of view, and it is useful to take the opportunity, such as is afforded to-day, of reminding the world that there is at least one branch of science which is wholly directed to the good of man, to the cure and elimination of disease and the prevention of untimely death. Up to the present, even if war is taken as a criterion, medical science in its work for the protection of man against disease and for his defence against injury has nothing to fear from comparison with that prostitution of the physical sciences which has been concerned with the production of methods of destruction.

In this beneficial work we proudly proclaim Jenner as an outstanding and successful pioneer.

TUBERCULOSIS IN INDUSTRY: AN EPIDEMIOLOGICAL STUDY*

PRELIMINARY REPORT

BY

ALICE STEWART, M.D., F.R.C.P.

AND

J. P. W. HUGHES, M.D., D.P.H.†

With the assistance of

W. E. C. Brooksbank† and Daphne Coulthard†

(From the Institute of Social Medicine, Oxford)

During the last 100 years information about death rates in various industries has steadily accumulated, and it is now clear that certain trades are constantly associated with a high tuberculosis mortality. In some cases the exceptional findings are due to a specific industrial hazard, such as silicosis, but in others no causal factors have yet been isolated. A typical example of the latter is the shoe trade, and, although the disease incidence is even higher in other occupations (Registrar-General's Decennial Supplements, 1890-1932), this has been selected for the first of a series of investigations into tuberculosis in industry.

So far working arrangements have been studied only in boot and shoe factories, but there are several reasons for believing that similar conditions prevail elsewhere, and that a systematic examination of other occupational groups will eventually reveal results very much like those which have been discovered during the course of this investigation. Meanwhile a brief account of the findings up to date may serve as a general introduction to the subject.¹

Present Investigation

The first indication that pulmonary tuberculosis was unduly prevalent in the shoemaking industry of this country was given in 1892, when the Registrar-General showed that the death rate among boot and shoe workers was nearly twice as great as the average for all occupied and retired males. Again, in 1902 and 1912 the Occupational Mortality returns for England and Wales showed a similar excess, and one of the first actions of the newly formed Medical Research Committee (forerunner of the present Medical Research Council) was to appoint a group of workers to investigate the industry.

In the M.R.C. report (1915) the investigators gave a detailed account of the manufacturing processes and described the general working arrangements in factories. They were satisfied that there was more pulmonary tuberculosis among boot and shoe factory operatives than in the rest of the population, and came to the conclusion that "the individual worker is predisposed to infection by the sedentary nature of his employment and possibly by the attitude he adopts at work." It was also suggested that "infection might be favoured by want of light, the presence of infected dust, and inadequate ventilation in the workrooms," but no attempt was made to produce any experimental or statistical evidence in support of these contentions.

Subsequently, despite the fact that the Registrar-General continued to report a high mortality, no further interest seems to have been taken in the subject until 1946, when

*Interim Report of an investigation initiated by representatives of the boot and shoe industry and public health authorities in Northamptonshire. The investigation, which is being financed by the Medical Research Council, is still incomplete.

†With a grant from the Medical Research Council.

the finding of the first Miniature Mass Radiography Survey in Northamptonshire once again drew attention to the prevalence of the disease among men and women employed in boot and shoe factories (Smith, 1947). On this occasion it was possible to make a direct comparison between shoemakers and other factory workers in the county, and it was found that, "compared with all other occupations, there was a statistically significant excess of newly discovered cases of active pulmonary tuberculosis in the boot and shoe industry."

The present investigation was a direct outcome of this survey and was undertaken at the request of the industry in order to discover whether the high rate of infection among boot and shoe operatives could be traced to working conditions or whether it is due to factors outside the control of the industry. Most of the work has been done in Northamptonshire, where shoemaking has long been the staple industry and where at present over one-third of the factory population is employed in this industry; but the section on general physique includes men from the neighbouring county of Leicestershire. The first part of the paper deals with recruitment into the boot and shoe industry, and shows how shoemakers as a whole compare with other workers in respect of their general physique and home environment. The second part relates to findings within the shoe trade, and shows how infection is transmitted from carriers to other workers.

I. Selective Recruitment into the Boot and Shoe Industry

It has often been argued that, because shoemaking provides a light occupation for men and, like old-established industries, is essentially a family trade, a vicious circle has been established which is alone sufficient to account for the high incidence of pulmonary tuberculosis amongst its working population. The argument runs as follows: in the first place, the nature of the work attracts men of poor physique, some of whom are suffering from chronic phthisis; these carriers, by propagating the disease in their homes, pass it on to their wives and children, many of whom, by reason of strong family tradition, become shoemakers and thus replenish the pool of infection.

Before the present investigation was begun no one had attempted to confirm or refute this theory, and even the suggestion that shoemaking was more of a family occupation than other trades was based largely on conjecture. Therefore, before embarking on a detailed study of factory conditions, an attempt was made to discover, first, whether an unusually high proportion of men with tuberculosis and/or low physique are recruited into the industry; secondly, how strong is the family tradition in the trade; and, thirdly, to what extent these factors are responsible for the high incidence of pulmonary tuberculosis among boot and shoe factory operatives.

Fitness for Military Service.—During the war years the Ministry of Labour and National Service instituted a scheme for examining men called up under the National Service Acts in order that they might be classified according to their fitness or otherwise for military service. The actual examinations were carried out by regional medical boards, who were responsible for placing men in four medical grades—namely, Grade I—fit for all forms of active service. Grade II—fit for active service but not for duties involving heavy strain. Grade III—unfit for active service: possible reservists. Grade IV—unfit for active service: rejected outright. Realizing that these records might contain valuable data relating to general physique of shoemakers, two batches of case sheets were inspected. The first referred to 22,620 men examined by one medical board in Northamptonshire, and the second to 33,350 men examined by two similar boards in Leicestershire. Both sets of records had been filed in chronological order, and a convenient sample from each batch was obtained by taking consecutive case

sheets of men employed in boot and shoe factories and pairing them with alternate records for men from other trades. The first sample comprised 2,785 Northamptonshire shoemakers and an equal number of controls, and the second comprised 1,635 Leicestershire shoemakers and 1,635 other men. When these records were inspected it was discovered that in each sample there was a slight but statistically significant difference between the medical grading of the two groups, the controls being more robust than the shoemakers (see Table I).

TABLE I.—General Physique of Men called up for National Service during 1942-3. Comparison of Boot and Shoe Operatives with Other Workers

Region	Occupation	Medical Grade				No. Examined
		I	II	III	IV	
Northamptonshire	Boot and shoe	66	18	8	8	2,785
	Other	74	14	6	6	2,785
Leicestershire	Boot and shoe	58	21	10	11	1,635
	Other	70	14	6	10	1,635
Both counties	Boot and shoe	63	19	9	9	4,420
	Other	73	14	6	7	4,420

Northamptonshire Miniature Mass Radiography Survey (1945-6).—Most of the men examined by the regional medical boards of the Ministry of Labour and National Service were under 40 years of age. In order, therefore, to obtain a more representative sample of shoemakers to compare with other workers the records of men examined by the Northamptonshire Mass Radiography Unit during 1945-6 were inspected. Apart from the high incidence of active pulmonary tuberculosis already reported by Smith (1947), there was nothing in these records to suggest that either heart disease or lung disease other than tuberculosis is more frequent among shoemakers than among other factory workers, and there was no evidence from the x-ray findings to suggest that leather dust causes pulmonary fibrosis. On the other hand, besides the "newly discovered cases of active pulmonary tuberculosis" mentioned in Smith's report there were several men who had already been notified, most of whom were found to be working in boot and shoe factories.

Family History of Shoemakers.—In order to discover to what extent shoemaking is a family trade, a sample of the Northamptonshire boot and shoe factory population and a control group of workers in other factories were asked about the occupation of their immediate relatives. The sample of boot and shoe workers comprised 1,233 persons from factories in various parts of the county, and the control group consisted of 1,027 workers from other factories in the same towns and villages. Each worker was also asked to state whether he or she knew of any near relative having had tuberculosis. In the boot and shoe sample over 90% of the workers who were interviewed stated that they had a near relative in the same trade, whilst in the sample taken from other industries over half had no family association with the trade in which they were employed. There were also a few more home contacts with tuberculosis among the shoemakers than among the other workers, so it is possible that the disease incidence in the shoe trade has been slightly augmented by passage of the disease through successive generations of workers.

Summary.—From the foregoing account it is evident that there are rather more tuberculosis carriers and men of sub-normal physique in the shoe industry than in most occupations. There also seems to be some indication that shoemakers in Northamptonshire, being more often interrelated than other factory workers in this area, are more frequently exposed to infection in their homes. Since shoemaking in other parts of the country also tends to be an old-established industry the family tradition so clearly demonstrated in Northamptonshire probably exists elsewhere.

II. Spread of Infection in Boot and Shoe Factories

Early in the present investigation it was decided that if infection was not being transmitted during working hours it should be possible to demonstrate a disease pattern in the boot and shoe working population which was dependent

solely on home conditions. On the other hand, if carriers of the disease were infecting fellow workers the disease incidence should be related to factory conditions.

Smith had already shown that, according to the results of the first survey of the Northamptonshire Mass Radiography Unit, the rate of infection in certain occupational groups was higher than in others. Since this finding suggested the possibility that working conditions might be contributing to spread of the disease, it was decided in the first instance to make a more detailed study of the mass radiography findings.

Between March, 1945, and Jan. 1, 1947, the Northamptonshire Mass Radiography Unit visited 162 boot and shoe factories and examined 15,911 skilled factory operatives, or 70% of the working population.* They also discovered 101 new cases of pulmonary tuberculosis, which represents an overall rate of 0.6% of the workers who were examined.

The number of newly infected persons in any one factory ranged from 0 to 14.3%, but since most of the factories employed fewer than 100 workers it was impossible to draw

TABLE II.—Incidence of Pulmonary Tuberculosis in Large and Small Boot and Shoe Factories (Mass Radiography)

Group	Size of Factory (Working Population)	No. Examined (Mass Radiography)	Cases of Tuberculosis	Pulmonary Tuberculosis Rate per 1,000
1	1-100	2,934	9	3.1
2	101-200	3,811	20	5.2
3	201-350	3,522	22	6.2
4	351-600	2,580	19	7.4
5	Over 600	3,064	31	10.1
Total		15,911	101	6.3

any conclusion from the experience of individual firms. When, however, factories of different sizes were compared it was found that the overall rate of infection was considerably higher in large factories than in small ones. This is clearly shown in Table II, in which the factories have been classified according to the number of persons employed.

According to this arbitrary arrangement the overall incidence of pulmonary tuberculosis in factories employing more than 600 workers (group 5) was over three times as great as in factories with fewer than 100 employees (group 1), factories of intermediate size showing a steady gradation between these two extremes.

Before deciding that this remarkable relationship was due to any fault in the working arrangements of large factories the following alternative possibilities were considered.

Age and Sex of Workers.—According to the records of the Mass Radiography Unit the age and sex constitution of each factory group shown in Table II was remarkably constant. Hence the greater incidence of pulmonary tuberculosis in large factories (which was found to apply to both sexes) was unlikely to be due to more "susceptible" persons in these factories.

Occupation.—Since boot and shoe factories are equipped with a uniform type of machinery and tend to relegate the same proportion of workers to each process, it was unlikely that the uneven distribution of infection was due to certain factories having unusual working arrangements. Such an explanation became quite untenable when it was found that the difference between large and small factories applied to every shoemaking occupation.

Regional Distribution of Large and Small Factories.—There were no factories with more than 600 employees in country

districts, so that it was possible that the higher rate of infection in larger factories was due to differences between urban and rural populations. There was, however, a sufficiently large number of small and medium-sized factories in both regions to show that, whether the factories were in towns or villages, the rate of infection was largely determined by the number of workers.

Factory Conditions.—The next discovery was that the disease incidence bore no relation to at least one estimate of working conditions in the factories. This particular estimate was made by regional representatives of H.M. Inspector of Factories, who visited 114 boot and shoe factories in Northamptonshire during 1945 and compiled a detailed set of records for the Working Party which had been appointed by the Board of Trade to report on the industry. The work was done by trained inspectors, who made systematic notes about the lighting, ventilation, method of dust extraction, sanitation, spacing of workers, cleanliness, and general working arrangements in each factory. On the basis of these notes the working conditions in each factory were graded as "good," "average," or "unsatisfactory." According to this assessment 24% of the factories with fewer than 200 operatives were thought to provide unsatisfactory working conditions, whilst in all the factories with more than 600 operatives the working conditions were well above the average. In these same factories the incidence of pulmonary tuberculosis, as discovered by the Mass Radiography Unit, was over four times as great in the large factories with "good" conditions of work as in the small factories, where the general layout was so much less "satisfactory." There remained one obvious difference between large and small factories which might account for the higher rate of infection in larger factories—namely, the greater number of persons in any one workshop. At first sight the more spacious rooms in large boot and shoe factories look more attractive and seem to offer better working conditions than rooms in small factories, which by comparison often seem dark and dingy. On the other hand, since infectious diseases usually spread more rapidly in large than in small communities, it was decided to explore the relation between number of workers per room and the incidence of pulmonary tuberculosis.

Size of Working Units in Large and Small Factories.—When the factories were arranged according to the average number of operatives per room a close correspondence between the overall working population and the size of the working units within the factories was found to exist. Thus, over 80% of the factories with fewer than 100 workers had fewer than 20 operatives per room, and all the factories with more than 600 workers had more than 60 operatives per room. It follows, therefore, that there is a close association between the incidence of pulmonary tuberculosis and the size of working units.* (See Table III.)

TABLE III.—Incidence of Pulmonary Tuberculosis in Boot and Shoe Factories with Large and Small Workshops

Workshops		Mass Radiography Survey		Pulmonary Tuberculosis Rate per 1,000
Workers per Room	Floor Area per Worker (sq. ft.)	No. Examined	Cases of Pulmonary Tuberculosis	
1-20	115 (10.7 m. ²)	3,474	10	2.9
21-30	91 (8.5 m. ²)	2,278	11	4.8
31-40	84 (7.8 m. ²)	2,763	14	5.1
41-60	82 (7.6 m. ²)	3,266	24	7.3
61-80	101 (9.4 m. ²)	2,205	21	9.5
Over 80	95 (8.8 m. ²)	1,925	21	10.4
Total	96 (8.9 m. ²)	15,911	101	6.3

More statistical work will have to be done before we can be sure that this is the fundamental cause of the high rate of infection in large factories. But the findings suggest that, under conditions which prevail in boot and shoe factories,

*In very small factories the space allotted to individual workers is usually greater than in larger factories, but where there are more than 20 persons per room the floor space per worker remains fairly constant. A more detailed study of the relation between floor area and workers per room is at present under consideration, and results will be published later.

*The published report of the medical officer of health for Northamptonshire, already referred to in the first part of this paper, covered the period March 1, 1945, to June 30, 1946, by which time 153 boot and shoe factories and 17 subsidiary factories (heel-making, closing, etc.) had been visited. In the following account all workers in subsidiary factories as well as the office staff of boot and shoe factories have been excluded, and the findings refer only to skilled operatives in boot and shoe factories.

operatives often become infected during working hours, and that in factories with large workshops carriers have actually caused local epidemics of tuberculosis.

Since there also seems to be some relation between rate of infection and factory size in the clothing industry (see Table IV) it is likely that the high death rate from pulmonary

TABLE IV.—Incidence of Pulmonary Tuberculosis in Large and Small Clothing Factories

Factory Size (Working Population)	No. Examined (Mass Radiography)		Pulmonary Tuberculosis (Rate per 1,000)	
	Males	Females	Males	Females
1-100	103	636	—	4.7
101-500	60	810	—	6.2
Over 500	166	1,312	—	9.2
Total	329	2,758	—	7.3

tuberculosis in other occupational groups (Registrar-General's Decennial Supplements, 1890-1932) is also due to spread of infection from carriers to fellow workers, and that there is nothing fundamentally different between the working arrangements in boot and shoe factories and those in other industrial communities. There can also be no doubt that mass radiography statistics contain valuable material for studying disease incidence in various occupational groups and that there is an urgent need for a more detailed study of these records.

Summary

An investigation has been made in Northamptonshire in which mass radiography records and other statistics have been explored. The investigation is still incomplete, but the findings to date suggest that the death rate from pulmonary tuberculosis in the shoe industry, which is high compared with all occupied and retired males but not much higher than other industrial communities, is due partly to selective recruitment and partly to working conditions.

There seem to be three aspects to selective recruitment: first, boot and shoe factories employ more men with chronic pulmonary tuberculosis than most other trades; secondly, the physique of the men is slightly subnormal; and, thirdly, there is a strong family tradition in the shoe trade, so that the workers are often interrelated.

There is no evidence of a specific industrial hazard in boot and shoe factories, and the death rate for diseases other than tuberculosis is below average.

Although workers with poor physique and chronic tuberculosis are found throughout the shoe industry, the incidence of active tuberculosis is not uniformly distributed, men and women employed in factories with large workshops contracting the disease more often than those who work in factories with small workshops.

In the clothing industry there is also more pulmonary tuberculosis in large factories than in small ones, so that it may yet be shown that size of working unit is an important factor in determining disease incidence in any occupation.

We are deeply indebted to Dr. Smith, medical officer of health for Northamptonshire, who was chiefly responsible for initiating the investigation and who allowed us free access to the records of the Northampton Mass Radiography Unit; also to the Incorporated Federated Associations of Boot and Shoe Manufacturers, the National Union of Boot and Shoe Operatives, the British Boot and Shoe and Allied Trades Research Association, H.M. Inspector of Factories, and owners of individual boot and shoe factories, who have provided us with invaluable assistance at every stage of the investigation.

SOME ASPECTS OF PARTIAL GASTRECTOMY

BY

JOHN HOSFORD, M.S., F.R.C.S.

Surgeon, St. Bartholomew's Hospital

Although a number of series containing several hundred cases of partial gastrectomy have been reported in detail from time to time in this country there are still some points which worry the occasional gastrectomist and about which gastric experts differ—points that have only been lightly touched upon. In the hope of understanding certain things more fully I have reviewed my own cases again recently, but the truth is very elusive.

The material under review is the first 200 consecutive cases of my own upon which a partial gastrectomy has been performed for a peptic ulcer at St. Bartholomew's or Hill End Hospitals. The first was in 1936 and the last at the end of 1947. The number is not large, but the cases have been carefully considered. They were not treated and operated on in any special wards or gastric clinic, but were simply included in the ordinary run of cases in a general surgical ward of a teaching hospital. The sex incidence is shown in Table I.

TABLE I.—Sex Incidence

	Males	Females	Total
Duodenal ulcer ..	99	8	107
Gastric ulcer ..	55	28	83
Anastomotic ulcer ..	9	1	10
Total	163	37	200

The proportion of duodenal to gastric ulcers is not nearly so high as in some reported series, probably owing to the fact that the former were not so readily accepted for operation, and certainly not until medical treatment had been given a very fair trial. The average age of the patients at the time of operation is shown in Table II. The youngest was a girl of 16 with a very tough adherent duodenal ulcer of seven years' standing which had resisted several courses of strict medical treatment. The oldest was a man of 69 with a duodenal ulcer.

TABLE II.—Average Age of Patients

	Males	Females
Duodenal ulcer	44 years	36 years
Gastric ulcer	48 ..	49 ..
Anastomotic ulcer	45 ..	25 ..

* One case only.

Twenty years ago the position of partial gastrectomy as a treatment for gastric ulcer was not fully recognized; ten years ago the same applied to duodenal ulcer. The operation is now fully acknowledged by physicians as well as surgeons, but it is still uncertain whether it will be replaced, at any rate for duodenal ulcer, by vagotomy before the true and whole cause of peptic ulceration is revealed and operations finally give way to a certain and easy cure by some balm, wave, atom, or other undreamed-of agent.

In an endeavour to obtain the best results from a procedure such as partial gastrectomy attention must primarily be given to the causes of post-operative mortality, and, secondly, to planning of the operation so that the type of gastrectomy chosen is that which will give the best results after weeks, months, and years. This paper is devoted to these two aspects of partial gastrectomy.

Cause of Death

In 1935 an investigation of post-mortem findings after partial gastrectomy (Payne, 1936) showed that the commonest causes of death in order of frequency were: general peritonitis, including infection around the duodenal stump; pulmonary infection; shock; and haemorrhage.

It is interesting to note that the causes of death after partial gastrectomy are still very similar. In three series of gastrectomies for peptic ulcer published in this country in 1948, giving details of 1,068 cases in which the operations had been done within the last ten years, the causes of death in order of frequency were: pulmonary infections; peritonitis from leakage; uraemia; embolus; and haemorrhage. It is worth while analysing each of these causes of death in turn and the steps taken to guard against them. In my present series, in which there was only one death (mortality 0.5%), every effort was made to guard against a fatality.

Pulmonary Infections

This was the commonest and most serious complication in the series. At least 20% of the cases had some degree of atelectasis after the operation and there was usually some superadded infection. In the earlier cases the diagnosis of atelectasis was rarely made, but I feel sure that this was because the condition was not so well appreciated or so carefully looked for. This applies to many conditions in medicine which appear to be occurring more commonly but are really only being recognized more frequently.

The treatment of atelectasis with infection can be divided into prophylaxis and treatment of the established condition. Under the former heading may be mentioned careful training in correct breathing, abstention from smoking, and treatment of any cough or bronchitis. The treatment of an atelectasis is to remove the plug of mucus which is obstructing the bronchus. Deep breathing, whether produced by inhalation of carbon dioxide or done by the patient's own efforts, is not nearly so good, either theoretically or in practice, as coughing. It tends to suck the mucus further in rather than push it out. With a high abdominal incision a patient does not readily cough; but a good nurse or physiotherapist can assist enormously by persuading and helping him to cough up a quantity of thick mucus which, if the patient was left to himself, would otherwise remain for days, acting as a bung. If one is fortunate enough to have the services of a physiotherapist skilled in pummelling the chest, so much the better, for this is a most valuable procedure in loosening the mucus plug before coughing it up. These simple procedures are often overlooked.

If the patient cannot or will not cough he can be made to do so most violently by the injection of 4 ml. of nikethamide intravenously: this should be combined with a few millilitres of thiopentone—enough to make him drowsy so that coughing will not hurt him too much. We have carried this out in only two cases in the present series, with satisfactory results so far as the lungs were concerned, but in the second case the great violence of the coughing produced a hernia through the midline incision, which was repaired at a later date. Aspiration of the mucus plug can be carried out through a bronchoscope; but this is not often called for, and was done only three times in this series.

The infection which so often follows atelectasis is dealt with by sulphonamides and penicillin. Seven years ago during the whole of one winter I used sulphonamides prophylactically in every case, but it was difficult to assess with certainty the value of this step, and now I use them only prophylactically in poor-risk cases.

Peritonitis from Leakage

There are two places from which a leak may occur in a Polya type gastrectomy—the duodenal stump and the gastro-jejunal anastomosis. It occurs more commonly from the former.

There is probably more variation in the technique of closing the duodenum than of any other step in the operation, and undoubtedly a great many of the methods are equally good and safe. There should be no difficulty in the duodenal closure in the case of a gastric ulcer where the duodenum is healthy and of average length and mobility, but in the case of a chronic duodenal ulcer this step is usually the most exacting in the operation and fraught with more danger afterwards than any other. However, by not sacrificing time and patience to speed, or improvisation to standard technique, a reasonably satisfactory closure can be made even in difficult cases. Nevertheless, a leak at the duodenal stump is an accident that continues to occur from time to time, and it still ranks high as a cause of death after partial gastrectomy, as it may lead either to general peritonitis or to a subphrenic abscess.

A simple manœuvre which I believe greatly lessens the danger of a leaking duodenal stump is the putting of a rubber drain into the abdomen. In no single instance in the present series of 200 cases have I failed to do this. Most surgeons look upon it as entirely unnecessary, and probably in 95% of cases it is; but it is a harmless procedure, and as, I believe, it saves a few lives and helps to reduce the mortality of the operation to nearer zero it is well worth doing. A drain must not be put in haphazard but must be most carefully placed (this applies equally to all parts of the abdomen). A "stab" incision is made on the right of the abdomen over the duodenum by cutting down on to the thimble finger, and a long thin corrugated rubber drain is introduced; it is placed so that it lies immediately inferior to and against the liver—it lies directly over the duodenal stump and then runs across the abdomen upwards and to the left to the site of the anastomosis. It is removed after four days if the abdomen seems quite satisfactory.

If a duodenal leak occurs the fluid is likely to track along the drain to the surface and a fistula to form: continuous suction is then applied to a rubber tube with several holes in it which is inserted just into the opening of the fistula; this prevents the fluid running all over the skin, with the consequent extreme soreness. The fistula then gradually closes. In four cases in this series there was a leak at the duodenal stump; but in none was it necessary to open the abdomen, and all recovered after a fistula had formed along the line of drainage.

Many surgeons dislike putting a rubber drain into the abdomen, the two chief objections being that it causes adhesions which may later lead to small-intestine obstruction, and, secondly, that it is as likely to do harm by letting infection in as it is to do good by letting infection (or other things) out. I do not for one moment believe that the second reason holds good, provided sepsis is observed. So far as adhesions are concerned they may cause obstruction later if a drain is placed near the centre of the abdomen and particularly suprapubically, but never when placed against the liver as described above.

Increased pressure from accumulation of fluid in the stomach or duodenum after operation is another possible cause of leakage occurring at the anastomosis or at the duodenal stump. This is obviated by leaving a Ryle's or similar tube in the stomach and using suction for 24 to 48 hours.

Uraemia, Embolus, and Haemorrhage

Uraemia.—In every case an estimation of the amount of urea in the blood is made, and if this is found to be raised or if for any other reason it is suspected that there is an alkalosis or acidosis, the alkali reserve and the blood chlorides are also estimated. In a number of cases (some of them quite unsuspected) the blood urea is raised, sometimes strikingly so. In Case 192 at one stage before operation it was as high as 530 mg. per 100 ml. (believed to be accurate). It is often due to a long-standing dehydration or to excessive use of alkalis or to vomiting. With rest, time, adequate fluids, and control of alkalis most cases will improve greatly and the blood chemistry return to normal; but there should be no hurry to operate provided there is no stenosis at the pylorus.

Embolus.—It has been most fortunate that in this series there has been no fatal pulmonary embolus. In one woman an embolus that must have been large very nearly caused death, but she gradually improved after papaverine. There seems little evidence for the old teaching that emboli commonly arise in the abdominal wall. It is far more probable that the most frequent site of formation is in the veins of the calf and foot; and certainly since the calves of all patients have been under careful observation one has been surprised at the number which have shown the characteristic pain or tenderness of thrombophlebitis. In some doubtful cases this has been confirmed by phlebograms. Active exercises and early ambulation are employed in the hope of preventing thrombosis. Heparin and/or dicoumarol are used as a routine when thrombosis is detected, but not as prophylactics.

Haemorrhage.—Haemorrhage at the suture line of the anastomosis is always a possibility, though it should not occur if care is taken. In every case the clamps which are used are not only loosened but are taken off after the posterior row of sutures has been completed. All bleeding points can then be clearly seen and ligated, especial care being paid to the lesser curve of the stomach, even though the left gastric artery has been well and truly tied. Taking off the clamps makes the operation look less neat, but it is without doubt a safer procedure and the anastomosis is easier to complete. There has been no trouble or alarm at all about post-operative haemorrhage in this series except in Case 47, in which about a pint of fresh blood was vomited an hour after the operation, in addition to some blood which had already been aspirated from the stomach by the Ryle's tube. The patient, a woman of 47, with a duodenal ulcer, then made an uninterrupted recovery after a transfusion of blood.

Best Type of Operation

In an endeavour to determine the type of partial gastrectomy which will be found most satisfactory it is obviously necessary to determine and compare the results of operations done by a variety of methods. In assessing and classifying the results of any operation so many factors have to be taken into consideration that nearly always some difficulty arises. A surgeon who grades the results of his own operations may be too optimistic owing to his surgical enthusiasm, while another may be too modest to claim the wonderful results of the enthusiast.

In all of the 200 cases a similar type of partial gastrectomy has been performed, in that the open end of the duodenum has been invaginated and a blind end formed. But at the anastomosis there has been a variation of method, for, although an end-to-side union between the remains of

the stomach and jejunum has been made in each case, the arrangement and details of this step have varied. It has been carried out in the five different ways shown in Table III and in the diagrams.

TABLE III.—Types of Anastomosis Used

A. Retrocolic anastomosis with valve	18
B. Retrocolic anastomosis without valve	77
C. Antecolic anastomosis with the afferent loop to the greater curvature without valve	6
D. Antecolic anastomosis with the afferent loop to the lesser curvature with valve	23
E. Antecolic anastomosis with the afferent loop to the lesser curvature without valve	76

Most surgeons seem to keep to one type of anastomosis, are usually quite satisfied with it, and believe it to be the best. Lake (1948) almost invariably does a retrocolic anastomosis with a valve, and indeed was one of the earliest to do this, so that the operation is often, and rightly, known by his name. Ogilvie (1947), who does a similar operation, admits that an antecolic anastomosis is a satisfactory operation when a moderate amount only of the stomach has been resected, but says that, "when the gastrectomy is not merely radical but also valvular, an anterior anastomosis is incompatible with proper routing of the afferent jejunal loop." On the other hand, Wells and Brewer (1948), who do a very radical gastrectomy with excellent results, prefer an antecolic anastomosis with a valve; and Visick (1948), who has reported in much detail his series of over 500 cases, always does an antecolic anastomosis without a valve: he leaves very little of the stomach, and the functional results of his cases are also excellent.

The obvious conclusions to be drawn from these facts are that good results are being obtained with either an antecolic or a retrocolic anastomosis and with or without a valve.

Results

Of the 199 patients in this series who survived the operation the results after a period of between one year and eleven years are available in 177.

To make an exact classification of results after partial gastrectomy is very difficult. They can be divided quite simply into good and bad, but there are so many degrees of goodness and badness that this is inadequate. It is easy to subdivide them into a greater number of grades, taking into consideration such things as age, work, social conditions, psychological outlook of the patient, as well as the position, size, and chronicity of the ulcer, etc.; and this is possibly wise when the purpose is purely to give an account of the results of partial gastrectomy. Here, however, I am largely absolved from many of these difficulties, because I am not so much endeavouring to say how good or how bad the results of partial gastrectomy are as striving to compare the results of one type of gastrectomy with another.

I have divided the results arbitrarily into three groups: (1) excellent, where the patient is free from all trouble and well in every way; (2) satisfactory, where there are some residual symptoms of a greater or less degree but where the patient is able to continue at his work and is definitely improved as a result of the operation; and (3) bad, where the patient is worse or no better than before operation. As years go by a patient is more likely to improve than to

deteriorate, and some who could previously have been in group 3 are now rightly placed in group 2, and similarly some have moved from group 2 to group 1. A continuous follow-up of all patients has unfortunately not been carried out, and the number of patients in whom a result is not known (8%) is somewhat high; but there have been great difficulties in the London area with evacuation and population movements, and returned letters marked "house destroyed" have not been rarities.

For the purpose of simplicity the results from one to eleven years have all been put together. The results for all types of gastrectomy for gastric, duodenal, and anastomotic ulcer according to the above grouping are shown in Table IV.

TABLE IV

Result	Cases	Percentage of Cases Followed up
Excellent	128	72
Satisfactory	45	25
Bad	5	3
Died in hospital (operative mortality)	1 (0.5%)	—
Died of intercurrent disease a year or more later	5 (2.5%)	—
Not traced	16 (8%)	—
Total	200	

Table V gives the results of the antecolic and retrocolic anastomoses grouped together and of those cases with a valve (erroneously called Hofmeister) and without a valve grouped together. The results in these several groups are

TABLE V

	Result		
	Excellent	Satisfactory	Bad
Retrocolic anastomosis	59 (74%)	16 (21%)	4 (5%)
Antecolic anastomosis	69 (70%)	29 (29%)	1 (1%)
With a valve	24 (69%)	10 (28%)	1 (3%)
Without a valve	104 (73%)	35 (24%)	4 (3%)

so similar as to suggest that no one type of anastomosis has any appreciable advantage over another, and that the addition of a valve does not make any significant difference. We have to consider the results not only months and years afterwards but also in the first few days after the operation, while the patient is still in hospital. At this time there is not, so far as I can detect, the slightest difference in the comfort of the patients or the smoothness of their convalescence whatever the kind of anastomosis, so long as it has been properly done.

Many objections to one or other type of anastomosis are theoretical and are not based on a careful study of symptomatic results. The importance of peristalsis seems sometimes to be forgotten and intestinal contents to be thought to move along by the same mechanism as the water in a garden hose.

The feeling of fullness with or without nausea after meals can be shown by radiographs to occur either with a slow emptying or with a rapid emptying of the stomach into the jejunum, though it is commoner with rapid emptying. It is often said that the feeling of fullness is due to part of a meal entering the afferent loop and distending the duodenum; but against this are the facts that in some people screening of a barium meal after partial gastrectomy will show some barium entering the duodenum without the patient being aware of it, while in others the patient experiences the feeling of fullness without any barium being observed to enter the duodenum at all. The clinical result is more important than the radiological. These remarks appear to apply equally to a retrocolic or an antecolic anastomosis.

A number of advantages are attributed to a "Hofmeister" valve: (a) It obviates the feeling of fullness by preventing food entering the duodenum; but the fallacy of this has just been mentioned. (b) It delays the emptying of the stomach because the exit is smaller; but this is fallacious, because the size of the exit is really the width of the jejunum at the entrance to the efferent loop. (c) It prevents, or at least diminishes, the regurgitation of bile into the mouth. From the results of my cases in which a valve has and has not been used there does seem to be slight statistical evidence for the belief that the last-mentioned is true. When food passes quickly out of the stomach the latter may be empty when the bile reaches it from the duodenum, and, should the patient be one whose stomach is intolerant to bile, regurgitation is likely to occur. If, however, a valve has been made, the flow of bile along the jejunum is so directed that it may pass the opening into the stomach without entering the latter at all.

Summary

A series of 200 cases of partial gastrectomy for peptic ulcer is reviewed with special reference to the causes of post-operative mortality, and to the comparative merits of an antecolic and a retrocolic anastomosis.

The commonest (so believed) causes of death after partial gastrectomy in this country are reviewed and means for preventing them discussed.

Emphasis is laid on the value and importance of draining the peritoneal cavity after partial gastrectomy.

It is unsound and apt to lead to error to compare the results of one type of operation performed by one surgeon with a different operation performed by another surgeon.

Figures are shown comparing the symptomatic results of antecolic and retrocolic anastomoses in this series. It is believed that the results are equally good.

There is little practical evidence that a valve at the anastomosis makes much difference to the symptomatic result, except possibly by decreasing the liability to bile regurgitation.

I am much indebted to a series of house-surgeons and chief assistants for their painstaking work in looking after these patients; but I owe an even greater debt of gratitude to the nurses for their endless skill and care, without whom many patients would have perished. They are far too numerous to name, but I make special mention of Miss E. M. Constable, sister of my male ward for almost the whole period.

The National Council for the Unmarried Mother and her Child has published a *Directory of Homes and Hostels* in which those organizations and institutions existing primarily for the care of unmarried mothers and illegitimate children are listed, together with information on their scope, limitations, and methods of admission. The list includes all the Homes and Hostels which the N.C.U.M.C. has been able to trace, whether affiliated to it or not. Homes which are primarily shelters have been omitted even though they may occasionally take a case of this type. The *Directory* is in three parts. First is the main list of Homes and Hostels, with particulars, arranged under counties, with London at the end. Then comes a classified list showing Maternity Homes (confinements take place in the Home), Before- and After-care Homes (confinements take place in hospital), and After-care Homes. Finally there is a general index. Although the denomination of the Homes is given where applicable, in nearly every case Homes will take cases of denominations other than their own. The *Directory* is not intended to facilitate the direct approach of outside agencies to Homes without prior reference to social workers. This would not be in the interest of either patients or institutions. Rather is it intended to facilitate the work of all in this field. The National Council would be grateful to hear about inaccuracies and omissions, and to receive criticisms and suggestions on how the list could be improved. The list may be obtained for 2s. 6d. from the N.C.U.M.C. at 21, Coram Street, London, W.C.1.

PERFORATION OF THE RECTUM

BY

J. D. T. JONES, M.S., F.R.C.S., F.R.C.S.Ed.

*Assistant Surgeon, Royal Victoria Infirmary,
Newcastle-upon-Tyne*

Traumatic perforation of the rectum in civilian practice is not a common injury. The literature on the subject is scanty, especially in this country, and consists largely of single case reports. This is not surprising, for very few surgeons see more than one case. In the ten-year period 1938 to 1947 four cases of perforation of the rectum have been treated in the surgical wards of the Royal Victoria Infirmary; the total number of surgical admissions during this period was 74,000.

Of these four cases three have come directly under my care; one was the result of perforation by an enema tip, one occurred during sigmoidoscopy, and one followed impalement on a broom-handle. The fourth case was also an enema injury.

Anatomical Details

Whatever the wounding agents may be, the resultant perforations are either extraperitoneal or intraperitoneal, and their management presents many problems which are peculiar to this region. Anatomically, the rectum is for the most part unprotected by peritoneum, it traverses a tissue which is highly vulnerable to infection, and it is difficult of surgical access. The pelvic floor, through which the rectum passes, is shaped rather like a trough, the sides of which are formed by the levator ani and coccygei originating from the internal surfaces of the pelvis on each side and joining in a median raphe below. The triangular anterior wall is formed by the urogenital triangle, while the triangular posterior wall is formed by the sacrum and coccyx. Over these structures the pelvic peritoneum is loosely draped as a cover. The potential space which exists between the pelvic floor and the pelvic peritoneum is known as the infraperitoneal space; should this space become distended with pus or blood rigid fascial planes will prevent its expansion in any direction except superiorly.

Laterally, the fascial planes are formed by the medial investment of the levators; these layers join inferiorly over the raphe and become continuous at the rectal and urogenital outlet with a similar layer of fascia loosely investing these viscera, the endopelvic fascia. By common usage the term fascia propria is applied to the rectal sheath of the endopelvic fascia. Anteriorly, the levator fasciae fuse with the deep layer of the urogenital triangle and posteriorly with the sacrococcygeal fascia.

Expansion of the infraperitoneal space is therefore limited inferiorly, laterally, anteriorly, and posteriorly by fascial planes, but is unrestricted superiorly. Even the pelvic peritoneum, however, is rather firmly adherent laterally along the line of origin of the levators at the so-called "white line," where levator fascia fuses with obturator fascia; it is most loosely attached over the sacral promontory on each side of the rectum, and it is here that the infraperitoneal space readily communicates with the retroperitoneal space, and infection arising in one may easily spread to involve the other.

Surgical Treatment

These anatomical details vitally affect the surgical treatment of extraperitoneal perforations. Free drainage of the perirectal cellular tissues is essential if spreading infection is to be avoided; adequate exposure of these tissues can be obtained by an incision parallel to the side of the sacrum and coccyx, dividing the fibres of the gluteus maximus near

its origin. Removal of the coccyx is not necessary in most cases, and indeed coccygectomy may be followed by unpleasant sequelae, such as intractable pain in the scar. Some maintain that adequate drainage can be obtained by a transverse curved incision inferior to the tip of the coccyx and incision of the fascia propria by blunt dissection. Having exposed and divided the fascia, it will be possible in some cases to demonstrate the perforation in the bowel wall; if it is readily found and is large it should be sutured, but if it is small and cannot be easily seen it need not be sutured, because contraction of the muscle fibres will bring its edges together and allow healing.

Opinions differ considerably about the value of a temporary colostomy as a part of the treatment. My feeling is that in any but the most trivial injuries it confers an additional safeguard which should never be omitted whether the perforation be extraperitoneal or intraperitoneal; its purpose is to divert the faecal current and place the rectum at rest by preventing any newly formed faeces being packed into it and distending its walls. In addition, the rectum should be drained from below by stretching the external sphincter and stitching in a large soft rubber tube; this should reach up for an inch or so beyond the level of the perforation.

Perforation by Enema Tips

Twenty cases of perforation of the rectal wall by enema tips have been reported in the literature. They fall into two groups: (1) pregnant women at term, and (2) persons from the sixth decade on.

Perforation of the normal bowel of the conscious patient can take place without the patient feeling much pain and without the use of much force; this is especially true of the older age groups, and of these 20 cases more than half were 55 or over. Twelve of the 20 cases were extraperitoneal, with five deaths (mortality 41.7%), and eight were intraperitoneal, with three deaths (mortality 37.5%).

While these cases are rare, it is impossible to guess at the real number that have occurred, because they form a group of cases that are only reluctantly spoken of and rarely reported. The perforations that do occur are generally complicated by the admission of the highly irritating enema solution into either the pelvic cellular tissues or the peritoneal cavity. In the absence of adequate treatment the result is either a fulminating pelvic cellulitis or a chemical peritonitis which turns very quickly into a purulent peritonitis from faecal contamination. Occasionally the solution has been injected beneath the mucosa or muscularis, and this has caused widespread sloughing of the rectal walls, with subsequent cellulitis and later stricture formation.

Case 1

A previously healthy man aged 74 was admitted with acute appendicitis of 48 hours' duration. An acutely inflamed non-perforated retrocaecal appendix was removed and he made a good immediate recovery. On the evening of the fourth day after operation a nurse gave him a soap-and-water enema by means of a Higginson syringe with a bone nozzle. About 6 oz. (170 ml.) of enema solution was injected. A few minutes later he felt a violent pain in his perineum and left groin; this persisted, became more severe, and radiated to his left loin and lower abdomen. He felt ill and nauseated. I was asked to see him six hours later. Examination at that time showed that he was very ill. The appendix scar was healthy, but the skin in the perianal region, perineum, left groin, left iliac fossa, and flank was dusky red, oedematous, and extremely tender, and there was well-marked left-sided abdominal guarding.

Immediate operation was advised: proctoscopy, performed under the anaesthetic, showed a relaxed external sphincter with copious mucoid discharge from the bowel. On the left wall of the anal canal, $\frac{1}{2}$ in. (1.9 cm.) from the anal a circular clean-cut perforation $\frac{1}{4}$ in. (0.85 cm.) the nozzle of the Higginson syringe fitted

perforation. The perforation extended through all coats of the bowel, and a vertical track passed upwards from its outer extremity in the perirectal tissues alongside the rectal wall for approximately 2 in. (5 cm.). The rectal mucosa was acutely inflamed, oedematous, and crepitating; the upper limit of these changes was not ascertained.

An incision was made alongside the coccyx on the left side and extending down through the left ischio-rectal fossa to the posterior anal margin; the posterior fibres of the levator ani were divided, the fascia propria incised, and the perirectal cellular tissues widely exposed. The perforation was identified, but owing to the sodden and friable condition of the bowel wall no attempt was made to suture it. The cellular tissues contained enema solution, and there were, in addition, acute inflammatory changes with already, in several places, greenish slough formation; the whole area was irrigated with hydrogen peroxide, dusted with sulphathiazole powder, and lightly packed with gauze.

A muscle-cutting incision was then made in the left iliac fossa; the extraperitoneal tissues contained thin turbid crepitant fluid, and similar fluid was present in the peritoneal cavity; there were several patches of green slough on the back of the anterior abdominal wall in the suprapubic region; the rectum and lower 2 in. of sigmoid colon were acutely inflamed, oedematous, and covered with large fibrin flakes. A large rubber tube was placed down to the pelvis and brought out through a separate small midline incision; a left iliac spur-type colostomy was then performed and opened immediately. The patient's condition at the end of the operation was critical; in the next few hours the cellulitis spread to involve almost the whole of the abdominal wall and lower part of the chest wall. Intensive administration of anti-gas-gangrene serum and soluble sulphathiazole intravenously appeared to have no effect whatsoever, and death took place eighteen hours later from overwhelming toxæmia.

Case 2

This case report is taken from the hospital records, which are unfortunately incomplete. This patient, a man aged 65, had been confined to bed at home for some days because of anginal attacks. He became constipated and was given a soap-and-water enema by the district nurse. This was administered by means of a Higginson syringe with a boné nozzle. During the administration he felt a sudden violent pain across the lower abdomen and in the left iliac fossa; this was accompanied by severe nausea and vomiting. He was admitted to hospital twelve hours later and was then very ill and collapsed; the exact cause of his condition was apparently not appreciated before operation. This was performed two hours after admission. It was then seen that the pelvic peritoneum was raised up by a large collection of greenish frothy fluid in the pelvic cellular tissues; this fluid was obviously enema solution. A left iliac Mikulicz-type colostomy was performed and opened immediately; the pelvic cellular tissues were not drained. Death occurred eight hours later.

These cases emphasize once again the dangers involved in the use of a Higginson syringe with a hard nozzle of any kind; they also emphasize the extreme gravity of this type of injury. Adequate surgical treatment in Case 1 had no apparent effect on the course of the infection, and, moreover, it would seem that a successful outcome can only be expected if the catastrophe is recognized and treated immediately. A delay of even seven hours would appear to make a fatal result almost inevitable.

Perforation during Sigmoidoscopy

Perforation of the rectum during diagnostic or therapeutic procedures is probably very rare and little has been written about it. While perforation is more likely to occur in cases presenting weakening of the bowel wall by disease, many cases have been reported without any discoverable lesion in the bowel. Thus, in a series of 46 cases reported by Andresen (1947), 21 showed no rectal lesion, 13 showed carcinoma, five diverticula, three ulcerative colitis, two polyps, and one each lymphopathia venereum and haemorrhoids. In this series 19 died and 27 recovered, giving a

mortality of 41.7%. The mortality rate is closely related to the time interval between perforation and operative repair. In Crohn and Rosenak's (1936) series the mortality was 47% if operation was done within seven hours of perforation; delay beyond this period results in a generalized septic peritonitis, with a mortality approaching very nearly 100%.

Diagnosis.—In most cases diagnosis is made at the time of perforation; the rent may actually be seen or a loop of small bowel or other organ may come into view when the end of the sigmoidoscope has passed completely through the rent. In a few cases there has been no suspicion of perforation at the time of the examination. Furthermore, there may be a delay of several hours in the onset of symptoms suggestive of perforation; an immediate onset of acute pain occurs only in about half the cases, even though subsequent operation shows that there has been a complete rent in the bowel wall. Once perforation is suspected ancillary methods of diagnosis may prove helpful. A flat x-ray film of the abdomen may show gas under the diaphragm; the sigmoidoscopy may be repeated and the rent seen. Air inflation during this procedure should be avoided if possible, as it may increase the risk of spreading infection.

Case 3

This patient was a previously healthy man aged 64, with a history of recent onset of ill-defined left-sided abdominal pain accompanied by diarrhoea and the passage of mucus but no blood per rectum. No abnormality was discovered on clinical examination, but a routine barium enema and sigmoidoscopy were advised.

Sigmoidoscopy was performed a few days later by a surgical resident. There was no abnormality, apart from some congestion of the mucosa in the recto-sigmoid region: a punch biopsy of this was taken from the anterior rectal wall, approximately 12 cm. from the anal margin. No suspicion of perforation of the rectal wall arose during this manipulation, which was of course performed without an anaesthetic.

Approximately four hours later the patient was seized with intense pain across the lower abdomen, accompanied by extreme rectal tenesmus, nausea, and vomiting. During an attack of straining he developed a prolapse of the rectum 4 in. (10 cm.) long; this was reduced by the house-surgeon, who, however, failed to notice whether the prolapsed portion showed any evidence of perforation. Reduction of the prolapse did not relieve his symptoms, and I was therefore asked to see him, eight hours after the sigmoidoscopy.

He was now obviously a very ill man and in severe pain; the abdomen was completely immobile and there was diffuse tenderness and board-like rigidity. The perineum was normal: there was no bleeding from the rectum, but a profuse discharge of clear mucus. No tear could be felt within the reach of the examining finger. It was also noticed that extensive surgical emphysema affected the neck and upper part of the anterior chest wall. In view of its distribution it was felt that this was probably due to the rupture of an emphysematous bulla during straining at stool. A pre-operative diagnosis of intraperitoneal rupture of the rectum during sigmoidoscopy was made.

Operation was performed ten hours after the original sigmoidoscopy. A left paramedian incision was made: there was a large collection of thin yellowish sero-purulent fluid in the pelvis and in both flanks; a circular perforation $\frac{1}{2}$ in. (0.85 cm.) in diameter with clear-cut margins was found on the right antero-lateral surface of the pelvi-rectal junction, approximately 3 cm. above the peritoneal reflection. There was no other lesion of the large bowel to account for the patient's original symptoms, and these were presumably due to a mucous colitis. The perforation was closed with a purse-string suture of catgut and the pelvis drained with a wide sheet of corrugated rubber. A left iliac spur-type colostomy was performed and opened immediately. Apart from a moderately severe wound infection, the patient made an uneventful recovery; the colostomy was closed after two months, and

nine months later he was known to be well and with normal bowel action. Biopsy of the specimen removed at sigmoidoscopy showed a portion of normal rectal mucosa.

Comment.—This case emphasizes again the dangers inherent in the use of a sigmoidoscope. These dangers can be lessened, if not eliminated, by a thorough training in the use of the instrument, a sound knowledge of the anatomy of the area, gentle handling without force, and, above all, good lighting to visualize the direction of the intestinal canal. If good visualization is impossible owing to persistent angulation of the bowel, or to faeces, blood, new growth, or other objects obscuring the lumen, the examination should be discontinued.

Treatment.—If operation is decided upon it should be performed as soon as the patient has sufficiently recovered from the shock of perforation. Treatment consists essentially in suturing the perforation, draining the pelvis, and performing a proximal colostomy. In a very few cases it may be considered wiser to treat the patient conservatively: these will mainly be cases in which perforation has not been recognized for twenty-four hours or so, and in which localization of the infection already appears to be occurring.

Perforation by Impalement

These bizarre wounds are of interest because of their comparative rarity and possible sequelae. The methods by which they are sustained are as numerous as the instruments which cause them, but it is curious to note that the majority of reported cases resulted from a fall from a hay-loft on to the handle of a pitchfork. Men are affected in 75% of cases, and according to Habegger (1912) approximately half of them are farm-workers.

There is an anatomical reason for the occurrence of this type of injury; the thigh surfaces, the ischial tuberosities, and the soft parts surrounding the anus tend to form a funnel-like contour which directs penetrating objects, especially those that are blunt, through the anus into the rectum. Because of the oblique relation of the rectal wall to the pelvic outlet the anterior wall of the rectum is the most frequent site of perforation, and the reported cases fall roughly into one of five categories: (1) The impaling object merely enters the lumen of the rectum and causes an abrasion or tear of the mucous membrane only. (2) Penetration of the rectal wall occurs at a low level and the urethra in the male or the vagina may be lacerated. (3) At a higher level, penetration of rectum and bladder occurs without, however, entering the peritoneal cavity. (4) If the force is greater the bladder may be completely traversed and the impaling object enters the peritoneal cavity through the dome of the bladder. (5) High rectal or even sigmoid penetration occurs, missing the bladder altogether and reaching the peritoneal cavity direct.

The immediate effects are often surprisingly slight; there may be very little pain, bleeding, or shock, and this may be most misleading. The seriousness of these injuries depends largely on whether the peritoneal cavity has been penetrated or not: Habegger reported a mortality of 26.8% in 179 cases, but with peritoneal involvement the figure reached 78.5%.

Case 4

A youth aged 17 was admitted with a history that five hours previously he was walking downstairs in his dressing-gown when he slipped and slid downwards feet first: at the bottom of the stairs a broom had been left lying, and the handle of this went in between his legs and into his rectum. He immediately withdrew it, and as he did so felt an acute pain across the lower abdomen. Very free bleeding occurred from the bowel and severe rectal tenesmus developed.

On admission he looked and felt ill. The lower half of the abdomen was tender and rigid; the perineum appeared normal

and there was no bruising round the anal margin; the external sphincter was undamaged. There was still considerable bleeding and also a copious mucoid discharge. A diagnosis of intra-peritoneal rupture of the rectum was made. Sigmoidoscopy was not performed.

At operation, two hours after admission, the bladder was catheterized and 8 oz. (230 ml.) of clear urine withdrawn. On opening the abdomen free seropurulent fluid was found in the pelvis and there was a tear 1 in. (2.5 cm.) in diameter in the peritoneum of the recto-vesical pouch in the midline. This opening was enlarged laterally on each side, and a circular tear 1 in. in diameter was seen in the anterior rectal wall, 1 in. below the peritoneal reflection. The bladder was intact, but there were early inflammatory changes in the pelvic cellular tissues.

Owing to the position of the perforation deep in the pelvis, adequate suture proved impossible, a large sheet of corrugated rubber was therefore laid against the side of the bowel and brought out through the abdominal incision; the peritoneum of the pelvic floor was left unsutured. A soft rubber tube was inserted through the anus, and its proximal end was guided up to above the level of the perforation. A left iliac spur-type colostomy was then performed and opened immediately.

The patient made an uneventful recovery; the colostomy was closed after three months, and he was known to be well and with normal bowel function two years later.

Discussion

Important points in the management of these cases are to determine immediately whether the rectum has been perforated and whether there are injuries to other viscera, especially the bladder or urethra. If no gross blood is present in the urine serious bladder injury is unlikely, but if there is doubt cystoscopy should be performed.

The rectal laceration when found should be sutured if possible, adequate drainage provided, and a temporary colostomy performed. If the bladder is involved the rent should be sutured and suprapubic or transurethral drainage instituted, depending on the degree of injury.

TREATMENT OF PERFORATIONS OF THE OESOPHAGUS

REPORT OF THREE CASES

BY

LESLIE J. TEMPLE, F.R.C.S.

Assistant Surgeon, Liverpool Thoracic Surgical Unit

Perforation of the oesophagus, particularly of its thoracic portion, was until recently regarded as a condition associated with a very high mortality rate. Perhaps for this reason there has been little eagerness to diagnose the lesion in its early stages. Barrett (1946) stressed the possibility of early recognition and radical treatment for spontaneous perforation. Goligher (1948) proved that early suture of perforation of the pharyngo-oesophageal wall due to crushing between the gastroscope and the cervical vertebrae is feasible. Fish (1946) recorded the successful suture of a gunshot wound of the oesophagus.

Tearing by foreign bodies, including oesophagoscopes, still remains the commonest cause of perforation. Mosher (1935) reported 19 deaths in 938 oesophagoscopies, two of these deaths occurring among the 285 cases examined

for foreign body. Occasionally patients with perforations produced in this way survive, with the formation of empyemata or mediastinal abscesses, which have been successfully drained (Churchill, 1935; White, 1941; Adams, 1946; Dorsey, 1948). However, the majority of patients with such perforations have died. Case 1 below illustrates the fact that perforation of the thoracic oesophagus—even multiple perforation—can be dealt with successfully by primary suture.

Case 1

The patient, a man aged 39, was a criminal in the "escape" category serving a sentence of three years' penal servitude. He reported to the prison medical officer on Aug. 23, 1948, that he had swallowed three safety-razor blades five days previously, and complained of dysphagia and precordial pain. On other occasions in prison he had swallowed pieces of glass and half a spoon, which he had passed without difficulty.

He was admitted to hospital, and a radiograph showed one razor blade in the oesophagus and at least two in the abdomen. The same morning oesophagoscopy was undertaken and an attempt made to remove the blade. The endoscopist reported that a grip was obtained on the blade, but it broke on attempting to move it and only several fragments were recovered. Haemorrhage put an end to any further intra-oesophageal manipulations.

When seen on the afternoon of the 24th he was shocked and there were signs of a right hydropneumothorax, which was confirmed by x-ray examination. He was transferred to this unit and operation was undertaken immediately.

Anaesthesia was induced with thiopentone and curare, and the lungs were then distended by using a facepiece and bag before passing an endotracheal tube. A right tension pneumothorax developed, respiration ceased, and the pulse almost disappeared. On inserting a large-bore needle in the right chest air hissed out and the patient rapidly recovered. An endotracheal tube was then passed and anaesthesia maintained.

The right sixth rib was resected and a large quantity of fluid containing pus and altered food was aspirated from the chest. The right lower lobe appeared to be consolidated. The mediastinal tissues were inflamed, and the pleura overlying the mediastinum and oesophagus showed jagged tears in a number of places. On incising the mediastinal pleura the oesophagus was seen to be cut open from 2 in. (5 cm.) above the azygos vein to 4 in. (10 cm.) below it. The vein itself was intact, and to facilitate exposure it was doubly ligated and divided.

The oesophagus was then opened up by joining the main 6-in. (15-cm.) tear to several small ones above and below it. At the upper part of the slit area there was a large abrasion on the right side of the oesophageal wall, with some necrosis. On the left side of the oesophagus there were four deep slashes penetrating the mucosa and musculature into the mediastinal tissues but not opening into the left pleural cavity. A further abrasion was present on the posterior wall towards the lower end of the oesophagus. At this point a broken half of a razor was found and removed. The cuts on the left side of the oesophagus were sutured from inside that organ, using a single layer of interrupted silk and turning the edges of the mucosa into the lumen. A good repair was apparently obtained.

The incision on the right was then sutured, leaving the knots of the silk sutures within the lumen of the oesophagus so far as was possible. The necrotic-looking area was excluded by stitches and left outside the oesophageal lumen. The mediastinal tissues were widely opened up by forceps dissection into the right pleural cavity, and a closed water-seal drain was inserted up to the oesophagus with side holes for draining the pleural cavity. Sulphonamide and penicillin powder was dusted in and the chest wall was closed.

The patient was maintained on intravenous and later on rectal fluids. He was given penicillin, and his general condition improved greatly.

On Aug. 28, four days after operation, a small amount of fluid was given by mouth and it immediately appeared through

the tube draining his chest. He returned to parenteral fluids, and on Aug. 30 a laparotomy was performed. Three halves of razor blades were removed from various portions of his intestine, and a Kader-Senn gastrostomy was carried out. He was subsequently fed through his gastrostomy opening, but the lower lobe of his right lung failed to expand and he remained pyrexial.

On Sept. 6 bronchoscopy was performed, and a large amount of pus was sucked out of the right lower-lobe bronchus, following which pyrexia subsided and the lung re-expanded. In spite of this, on testing the healing of his oesophagus by giving him a small amount of water coloured with indigo-carmin the dye immediately appeared through his tube.

Since healing was unsatisfactory, oesophagoscopy was carried out on Sept. 21. The oesophagoscope was passed between two rows of sutures, which were clearly seen, but no fistula was apparent and there was no tendency to stricture formation. The oesophagus contained fragments of half-chewed apple, and on subsequent search of his room quantities of food and cigarettes were found concealed—this in spite of the fact that a warder was in constant attendance. Security measures were tightened up and his oesophagus now very rapidly healed, as shown by the dye test, and on Oct. 4 the gastrostomy tube was removed.

There was still a small sinus into his chest, but this was rapidly healing and there was good aeration of his right lung.

Accordingly he was returned to prison on Oct. 7, where he made good progress. He subsequently developed a small localized empyema in the anterior part of his right chest, presumably a residual pocket left by the expanding lung. It was found possible to deal with this without removing him from the surveillance that seemed to be so necessary for his welfare. Oesophagoscopy on Dec. 20 showed good healing and no stricture, although the sutures were still present.

Recovery in this case is somewhat surprising in view of the extent of the damage, the long delay that took place between perforation and repair, and the considerable degree of infection that had already occurred, as well as the uncooperative attitude of the patient, who was anxious to prolong his stay in hospital indefinitely.

Comment on Case 1

The treatment of this case can be epitomized as drainage of the mediastinum and repair and defunctionalization of the oesophagus. Drainage of the mediastinal tissues should always be into the pleural cavity, opening the mediastinal pleura from top to bottom. The posterior extrapleural route—unless it is to resemble a Sauerbruch thoracoplasty—cannot effectively drain the mediastinum. In an early sutured tear of the cervical oesophagus with only slight upper mediastinal involvement mediastinotomy might be considered justified, but as soon as the mediastinitis extends so that the drainage is no longer dependent thoracotomy would be necessary. In view of this and of the difficulty in appreciating the extent of the infection, it is probably wiser in all cases to open the thorax at the outset.

The ideal time for exploration seems to be either before complications can develop or as soon as measures have been taken to deal with such urgent complications as tension pneumothorax. The surgeon who believes he has perforated the oesophagus during an endoscopy should, if facilities are available, have the anaesthesia continued, turn the patient over, and open his thorax. In such a case it should be possible to proceed with a gastrostomy immediately. If the patient is not fit to stand a gastrostomy, rectal or intravenous feeding should be continued for a few days and then the gastrostomy performed. Even if primary suture is carried out disappointments are only too common, and are likely to remain so until the diagnosis is made before serious infection has intervened. Case 2 illustrates a tragedy of this type.

Case 2

A woman aged 54 was admitted to hospital complaining that she had swallowed a chicken bone on Sept. 21, 1948, and that it was sticking in her chest.

Oesophagoscopy was carried out the next day under a general anaesthetic. No foreign body was found, but an abrasion of the mucosa was seen low down in the oesophagus. She was returned to the ward and shortly afterwards, at 4 p.m., suddenly complained of difficulty with breathing and of pain in the left side and back. She was reported as being obviously shocked, and oxygen and nikethamide were administered. Her condition did not improve very greatly, respirations became increasingly difficult, and diminished air entry was noted on the left side.

On Sept. 23 she was somewhat easier. When seen later that day she was pyrexial, and obviously her oesophagus was perforated into the left pleural cavity. X-ray examination showed hydropneumothorax and mediastinal emphysema. There were many moist sounds throughout the right lung and no breath sounds on the left. The heart and trachea were displaced somewhat to the right. She was not fit to be transferred to the chest unit and was treated in the hospital of admission. A needle was inserted into the left chest immediately and attached to an under-water drain. Air bubbled up under pressure and there was a considerable improvement in her condition.

Operation was then undertaken. The seventh left rib was resected. The pleural cavity appeared to be grossly infected and large quantities of thin pus and fibrin clot were present. A hole was noted in the pleura just in front of the aorta, and through this area the mediastinum was laid widely open. Thin pus gushed from the interstices of the mediastinal tissues. On retracting the aorta a tear 1 in. (2.5 cm.) in length was seen in the posterior aspect of the oesophagus just above the diaphragm. This was sutured with five interrupted silk sutures, and a rubber tube leading to the mediastinal perforation, with side holes to drain the pleura, was inserted and attached to a water-seal. Penicillin powder was dusted in and the chest closed. Large doses of penicillin and a rectal drip were administered. Morphine and its derivatives were avoided owing to the considerable degree of lung oedema, and coughing was encouraged for the same reason.

When seen next day her condition had greatly improved. The left lung was aerating well, and fluid still escaped from the drainage-tube. Rectal fluids were being returned, and owing to the condition of her lungs intravenous therapy was contra-indicated. For the same reason I was not anxious to subject her to another operation, so a soft Ryle's tube was passed into the stomach and feeding was continued by that means.

She remained well until 10.45 p.m., when she suddenly collapsed while talking to somebody in the ward and died within a few minutes.

At necropsy the torn area in the oesophagus was found to be adequately sutured and watertight, but both lungs were very oedematous and the left lung was partly consolidated. There was of course mediastinitis and inflammation of the left pleural cavity. I believe that death in this case was due to the lung oedema of acute heart failure resulting from the effect of her severe infection and from toxic absorption. It was difficult to see what other measures could have been taken to prevent a catastrophe, but it is some encouragement to know that the suture itself was effective.

Conservative Treatment

Whilst it has been stressed that a perforation or a suspected perforation of the thoracic oesophagus should be explored without awaiting the development of signs of that condition, suspected perforation of the cervical oesophagus is possibly in a different category. Here the part concerned is under more direct observation and there may in some cases be a place for conservative treatment. No criteria can be laid down for this, and at the very first indication of infection or extravasation outside the oesophageal wall the surgeon must be prepared to explore the

oesophagus and suture the tear. Case 3 illustrates successful conservative treatment.

Case 3

A woman aged 20 reported at hospital on Nov. 6, complaining that whilst eating stew the previous evening a bone had stuck in her throat and had remained there ever since.

Under a local anaesthetic she was examined with a laryngoscope, but it was not possible to pass the upper oesophageal sphincter and no foreign body was found. She was kept in bed and developed a pyrexia up to 100.4° F. (38° C.); there was some fullness in the tissues of her neck. She was put on penicillin the same day. On Nov. 8 a radiograph showed the swallowed bone just above the sternum on the right, but there were no signs of surgical emphysema either on the radiograph or clinically. Under a general anaesthetic an oesophagoscope was passed with ease. Just below the sphincter on the right side there was an area of oedema and redness. On pressing the folds apart a piece of bone was seen lying on the surface of the oesophageal wall. This was gripped with forceps and a long spike 1½ by ¾ in. (3.2 by 1.9 cm.) was withdrawn from its position transfixing the wall of the oesophagus. A small piece of bone was also found lying loose; this was removed. After removal the small perforation made by the spike of bone could be clearly seen.

The patient was given 1,000,000 units of penicillin daily and, after twenty-four hours, sterile water by mouth. Her temperature subsided immediately after oesophagoscopy and remained down. At no time was there any x-ray evidence of surgical emphysema, and her clinical condition gave no cause for alarm. After ten days she was allowed a full diet and was discharged from hospital.

In this case there were very considerable doubts whether further surgery should be undertaken when such an obvious perforation of the oesophagus was seen, but the site was so accessible that had any infection arisen it would at once have been apparent and could have been dealt with. The conservative policy adopted was justified by the end-result.

Summary

The importance of early diagnosis and primary suture of instrumental or foreign-body tear of the thoracic oesophagus is discussed. Lines of treatment are suggested, and two cases are described, one of which had suffered multiple oesophageal perforations from a razor blade and had recovered after primary suture.

Conservative treatment for suspected damage to the cervical oesophagus is suggested, and is illustrated by a successful case.

My thanks are due to members of the Liverpool Chest Unit, in particular to Mr. F. Ronald Edwards for his assistance and advice with these cases, and to Mr. Horace Mather for his advice in the preparation of this paper.

The Government has issued a pleasantly illustrated pamphlet entitled *The Budget and Your Pocket* (H.M.S.O., 3d.) describing what money is collected from the taxpayer and how it is spent. It says that the tax money spent on health services is 7s. 9d. a family a week. The hospital service accounts for about 5s. a week of this, over half being the pay of doctors, nurses, orderlies, and other staff; rather over 1s. a week goes to general practitioners, and 9d. to the dentists; the remaining 1s. covers medicines, appliances, spectacles, eye testing, and so on. "It may seem strange," concludes the pamphlet, "to keep some prices high by taxation so as to raise money which is partly for a budget surplus to keep prices down. But that is exactly what must be done. . . . The final remedy will come when we are producing more, and producing it more efficiently so as to keep our prices down—earning more money, and getting more for it."

SIMULATED AMNESIA FOR IDENTITY TREATED BY ELECTRICALLY INDUCED EPILEPSY

BY

R. E. HEMPHILL, M.D., D.P.M.*Medical Superintendent, Bristol Mental Hospitals; Lecturer in
Psychiatry, Bristol University*

AND

J. R. STUART, M.B., Ch.B., D.P.M.*Senior Assistant Psychiatric Physician, Bristol Mental Hospitals*

Inability to recollect identity is commonly complained of in hysterical fugue states, and sometimes by borderline hysterics and malingers. It is occasionally seen after an epileptic fit or with serious organic brain damage or wasting.

Clouding of consciousness (as in epilepsy and concussion) or intellectual impairment (as in senility) is characteristic of the organic type. As an organic phenomenon inability to remember one's identity implies such a profound disturbance of brain function that memory, judgment, and even simple intellectual processes are bound to be impaired.

Inability to identify oneself, with clear sensorium and intact intellect, cannot be attributed to a local brain defect. Thus a patient who persists that he does not know who he is and has no recollection of his life's history up to the time of the examination, but is otherwise intellectually clear, is either feigning or suffering from a true hysterical amnesia. In the latter case it should be possible to restore memory easily by hypnosis or other usual psychotherapeutic procedures within a few days, especially if full use is made of the associations of everyday life, such as press news, sporting events, and the like.

Almost certainly, all continuously resistant subjects are malingers. It is very doubtful if a genuine psychological amnesia persisting for years has ever occurred, although this idea has proved a plot for various successful novels and screen plays. A good account of amnesic states is given by Parfitt (1944).

Malingering

We have never seen a case of "primary malingering"—that is, deliberate denial of knowledge of identity without some previous hysterical state. We believe that it is very rare and that it is likely to be used only in situations where an individual wishes to escape recognition and is unable to establish another identity or think of a better excuse. For this form of amnesia is bound to bring the individual immediately to hospital—where his movements will be restricted and he will be under the notice of the police—and to stir up interest and stimulate research into his past. Thus it will not be used by a criminal with a previous police record who wishes to escape detection for a recent crime; the fingerprint service and the B.B.C. would make it useless. Nor will a malingering simulate loss of identity near his home, where he can be recognized by others or confronted with his parents. The lie has purpose only if a patient wishes to make use of a hospital or plead a psychiatric excuse for conduct. Thus we find it used by hysterics who wander from home unable to face some situation, by ex-gaolbirds seeking temporary lodging, or by deserters from the Forces.

The pretence is difficult to keep up and can succeed only if the patient has had experience of being treated for hysterical amnesia and knows the kind of investigation that will be made and the questions he will be asked.

In our experience the simulation is always secondary, and is either the continuation of a hysterical episode—the patient keeping up the pretence after his memory has been restored because he finds it convenient to do so or because he cannot face the results of exposure—or is used by hysterics who have had previous attacks of genuine hysterical amnesia.

Hysterical behaviour is facilitated by previous attacks, and the pattern of each is usually the same. This is as true for psychic as for motor manifestations. Thus amnesic or wandering states are rarely isolated episodes in the history of the hysteric, and, after having occurred a few times, a very trivial stimulus may suffice to produce an attack. This probably accounts for the ease with which professional mediums pass into trances, for states of dissociation are easily induced by frequent repetition.

Hysterics feigning amnesia may even come to doubt their own reality and so develop a perplexed cloudy state. Our patient, for example, would repeat his name over and over again to himself, and told us subsequently that at one time he used to write down his real name on a small piece of paper and pin it to his pyjamas at night, lest he should forget it.

Simulated loss of identity is therefore a lie that comes easily only to the hysteric, and it may be a pattern of conscious behaviour in a certain situation established by a previous unconsciously motivated habit.

These cases are most difficult to treat. They handle hypnosis and narco-analysis in the most guarded way, and usually reveal false clues. They become more expert with every subsequent session. If the intravenous narcotic or ether is pushed they may feign sleep so that the drug will be withdrawn. They attempt to learn about contemporary life from the papers, the radio, and other patients, and are ready to point out that they have learned about past and current world affairs since entering hospital. This remarkable ability to learn and remember effectively rules out organic brain damage as a factor.

The man whose case is described below kept up his act for many weeks and in three different hospitals. He behaved true to type, improving in co-operation with every session, supplying more and more useless information. He was bold enough to describe real episodes of his life, withholding essential details. He spoke of his experiences in the R.A.F., of accidents and illnesses, described hospitals where he had been treated, and even suggested that he had been a male nurse. All these statements were true, but were given without dates or names of hospitals, so none of his clues could be followed up.

He suggested a name for himself which was false, but it was by this false name that he agreed to be known when he was admitted to hospital.

Case Report

The patient, a man aged 24, was admitted as a voluntary patient to Barrow Hospital, Barrow Gurney, near Bristol. His medical history as known to us at the time of his first examination there was as follows. On the night of June 22, 1948, he reported to the police in Bath, saying that he had a headache with loss of memory. He was taken to a hospital, and stated that he did not know who he was or where he came from, nor could he recollect any facts of his life before reporting to the police. He had some money, but was without identity card or ration book; there was no name or mark on his garments except a name—afterwards found to be incorrect—on his tie. He was dressed in flannel trousers, sports coat, shirt and tie, shoes, socks, and underclothes. He had no hat. Narco-analysis was attempted on several occasions at this hospital, and he was afterwards transferred to another hospital, where he underwent ether abreaction and other psychotherapeutic procedures. H

informed us that he was still unable to recollect anything relevant in spite of all attempts

Examination on his admission to our hospital revealed no organic disease or change in the central nervous system, and the electroencephalogram was within normal range. He had a well-healed operation scar of the left forearm, and his nose had been broken.

He gave a clear account of all events subsequent to being brought in by the police about six weeks before. He related episodes of his past life, which he said had been told him by doctors after sessions of ether abreaction and narco analysis. He stated that he had been an orderly in the R A F, and had had an injury to his left arm, for which he was treated. He was discharged from the R A F on psychiatric grounds, and later was a male nurse at a hospital "somewhere in the country." He gave the name and number of the ward in which he worked but not the name of the hospital. He gave the Christian names of many relatives, but not their surnames.

He persisted that he was most anxious to ascertain who he was and stated that his desire was to be made well so that he could return to work. While in hospital he read industriously. He showed no obvious concern about being in hospital, and his indifference to the seriousness of his condition was in marked contrast to the concern that he stated he felt.

Obviously further psychotherapeutic sessions were contraindicated, and we were able to prove that the patient was lying. He probably did not have an important criminal record, for he willingly allowed fingerprints to be taken and a description circulated in the *Police Gazette*. Proof of feigning was supplied in the following conversation:

Q—What would you do if I discharged you from hospital to-day with ten shillings?

A—I suppose go back to the doctor in Bath.

Q—But if I warned you that no hospital would accept you, how would you make a start in the world?

A—I suppose I would have to go to the police.

Q—How would you set about getting an identity card?

A—I suppose from the police.

Q—How would you get food?

A—I do not know.

Q—You must know. Please think. What would you do about paying for food as soon as you left hospital?

A—I do not know. I cannot remember. I suppose I would get help.

Q—Would you get a ration book, and if so where?

A—I would have to ask the police where to get it.

Q—What is rationing?

A—A system for the fair distribution of food.

Q—Then what is a ration book?

A—You forget that since I came to hospital I have read a lot to find out what I am and what I should do. I have studied *Picture Post* and other papers since 1939.

Q—Why 1939? What has that got to do with it?

A—I do not know. I cannot remember.

In this way he was caught. He probably knew about identity cards and certainly knew about rationing and the outbreak of war, although pretending that he did not.

He gave his consent to any measure being employed that could restore his memory, including electric convulsion therapy. We are not aware that induced epilepsy has been applied in this way before.

The rationale for induced epilepsy was as follows. During the post-convulsive phase of an epileptic fit neural function is re-established according to Jacksonian rules. Thus, after breathing has returned and while unconsciousness is still deep, spontaneous movements and motor restlessness appear. Speech functions return with a period of aphasia, knowledge of parts of the body is restored before that of external objects (Hemphill and Walter, 1941). The patient becomes aware of himself and therefore is able to establish his identity before he can be aware of his surroundings or has any other recollection of antecedent events. Thereafter there is an increasing awareness of external reality, with diminishing amnesia, finally, the amnesia contracts until it covers little more than the period from the onset of the fit until cerebral function has been fully restored.

Having regard to the order in which psychic functions return, it was fairly certain that our patient would recollect his name and address and probably something of his family affairs,

before brain function was sufficiently restored to enable him to remember that he must lie, in other words to apprehend the situation which demanded the lie and the implications of restored identity requires a much higher degree of cerebral integration and activity than merely to recollect name and address.

It was therefore probable that if the patient disclosed his identity in the post-epileptic state he would be unable to recollect that he had done so—for with cerebral function still low he would be unable to form clear memories, as is seen in alcoholism and in concussion—and that he would persist in his lie as soon as he had sufficiently recovered from the epileptic state. This is in fact what occurred.

Treatment

A major epileptic fit was induced electrically. As soon as breathing was re-established and he was responsive to external stimuli questions about his identity were repeated until finally he gave his name. As brain function improved he was able to give his home address, his brother's name, and his father's occupation. He then slept. He was interviewed 14 hours later, when he was completely free from the effects of the epileptic fit. He then said he could not remember anything about the treatment except that the electrodes had been applied to his head. When the name and address he had given were told to him he stared blankly and said they meant nothing to him. The interview then terminated. Check-up proved that he had disclosed his correct name and address. He was informed of this and told that in his own interests he must remain in a closed ward in case there should be a further fugue state. He still denied that the remembered name was correct. The following day he sought an interview, stating that he realized "the game was up," and he then gave a detailed account of his early life. Briefly this was as follows:

The Patient's Previous History

He had been employed in a large electrical firm in the Midlands. A few days before leaving home he had been offered promotion to a responsible post. He felt inadequate to take the post, but as his colleagues knew of the offer he felt that he could not refuse without loss of prestige. Further, he lived in constant dread of his father, whom he could not face. He decided to get away from his place of work and his home. There appears to have been a genuine fugue state similar to what had occurred on previous occasions. He stated that there had been a period of amnesia following mental stress in 1945, when the amnesia was cured by narco-analysis. There were other incidents of a similar nature. Early in 1948 he left home after a quarrel with his father, and was apprehended by the police in another town, where he was standing alone on a river bank. He appears to have feigned loss of memory, and was subsequently admitted to the county mental hospital, where he said he had difficulty in convincing the authorities of his correct name. He admitted that he had once been in the hands of the police as a juvenile for some minor civil offence.

From our assessment and his history, which was confirmed by his parents, he was above the average in intelligence, but always self-centred and prone to hysterical reactions. His home was comfortable. It appeared that the father had always expected much of the son. On the whole the patient enjoyed being in the R A F, and it is probably true that there was no amnesic episode until his arm had been injured.

Points of clinical importance in his history are: (1) The patient's basic personality was hysterical and immature, but in spite of poor adjustment at home there was no history of an amnesic episode until he actually came under medical treatment in the R A F. (2) The first attacks seem to have been true hysterical dissociation, with true loss of memory, and these were cured quickly by narco-analysis. (3) The patient improved on his medical knowledge by serving as a male nurse even after he had had hysterical fugue states. (4) His apparent loss of memory for identity appeared only after a wandering state had brought him well away from home. (5) It was easy for him to simulate loss of memory for identity, because he had had previous true hysterical episodes with hospital treatment. (6) His carefully conducted defence became stronger as he became more adroit at evading the issues with every attempt at psychotherapy.

Discussion

Induced epilepsy is likely to be of value only in the case of simulated inability to remember identity. The usual procedures should be employed in true conditions of psychogenic amnesia. Induced epilepsy is valueless in restoring truth in any other kind of lie (except perhaps hysterical mutism, deafness, or blindness) because it uses a neural phenomenon which makes the patient able to identify himself correctly before he is capable of remembering external events and sorting them out.

Summary

A case is described in which induced epilepsy was employed to establish identity in a patient who feigned amnesia for his name and the total previous period of his life. This type of amnesia and the neuro-physiological rationale of the treatment are discussed.

AN UNUSUAL CASE OF CHRONIC MYELOID LEUKAEMIA

BY

R. A. RUSSELL TAYLOR, F.R.C.S.

Medical Superintendent and Surgeon, Pinderfields General Hospital, Wakefield

The interesting feature of the following case is the response to treatment devised for a mixture of cirrhosis of the liver and myeloid leukaemia.

Case History

The patient, a man aged 61, was admitted to this hospital on March 13, 1946, with chronic myeloid leukaemia, marked splenomegaly, and ascites. A careful history revealed that he had been treated for pernicious anaemia since 1931, but the report of a blood count taken on Dec. 8, 1931, failed to substantiate this diagnosis. It was as follows: haemoglobin, 76%; red cells, 3,820,000; colour index, 1; white cells, 9,600 (polymorphs 75%, lymphocytes 15%, eosinophils 1%, basophils 2%, large hyaline cells 2%, transitional cells 5%).

The next report to which we had access was dated March 11, 1941, and the blood count was as follows: haemoglobin, 98%; red cells, 4,300,000, colour index, 1.14; mean diameter of red cells, 7 μ ; nucleated red cells, 1,000 per c.mm.; poikilocytes and polychromatic cells; white cells, 26,000 (polymorphs 56%, eosinophils 1%, basophils 2%, lymphocytes 9%, monocytes

6%, neutrophil myelocytes 20%, eosinophil myelocytes 1%, basophil myelocytes 3%, myeloblasts 2%). The report stated: "The white cell picture tends towards that of chronic myelogenous leukaemia."

On June 14, 1941, the white blood count had increased to 36,000, but the differential percentages remained constant.

No further reports were available until Nov. 3, 1944, when the blood picture was: haemoglobin, 69%; red cells, 3,420,000; colour index, 0.99; nucleated red cells, 1,270; reticulocytes, 2.2%; white cells, 35,700 (polymorphs 44%, eosinophils 1%, lymphocytes 25%, monocytes 12%, myeloblasts 4%, neutrophil myelocytes 11%, eosinophil myelocytes 1%, basophil myelocytes 2%). Blood counts were then taken at fairly regular intervals; these are recorded in Chart 1. In the differential counts the percentage of myelocytes varied between 6 and 30%, while that of the myeloblasts varied between 1 and 23%.

The most characteristic blood count was that taken on Aug. 24, 1948, and is therefore given in detail: red cells, 3,100,000; haemoglobin, 61%; colour index, 0.99; white cells, 17,130. Differential count was as follows: neutrophil polymorphs, 9,350 (55%); basophils, 510 (3%); neutrophil "stuffs," 850 (5%); neutrophil metamyelocytes, 1,800 (10.5%); neutrophil myelocytes, 3,150 (18.5%); myeloblasts, 950 (5%); lymphocytes, 340 (2%); monocytes, 0; normoblasts, 90 (0.5%); erythroblasts, 90 (0.5%).

On March 14, 1946, paracentesis abdominis was performed and 12 pints (6.8 litres) of ascitic fluid were removed. The very marked and extensive oedema of both lower limbs was not affected in any way even after massage. On March 15 a blood transfusion of 2 pints (1.14 litres) of blood was given, and this was repeated on March 29, April 4, and May 24. The patient also received massive doses of iron daily.

Paracentesis abdominis was repeated on April 16, and 14 pints (7.95 litres) of ascitic fluid were removed. This process was repeated at rapidly diminishing intervals during the next three months, until as much as 24 pints (13.6 litres) were being removed every five days. The exact dates and amounts are

CHART 2.—Amounts of ascitic fluid withdrawn.

CHART 1.—The blood count.

given in Chart 2. The protein content of the ascitic fluid varied between 2 and 2.5 g. %.

By this time the patient was markedly emaciated and the abdomen was grossly distended by ascitic fluid and a large spleen, which reached right down into the pelvis. His liver, however, was only slightly enlarged.

On July 2 an estimation of the plasma protein gave a reading of 5.1 g. %, and a hippuric-acid test showed that the amount of hippuric acid passed in the four-hour period was only 2.7922 g., with the maximum excretion in the second hour. It was therefore decided to give 1 g. of choline chloride and 1 g. of cystine twice daily. This was done on the assumption that choline and cystine can help to prevent hepatic cirrhosis due to a very low protein intake.

The hippuric-acid tests were repeated, with the following results:

Date	Amount of Hippuric Acid Passed in 4-hourly Period	Maximum Excretion
12/7/46	2.7504 g.	3rd hour
19/7/46	3.1794 g.	3rd "
30/7/46	3.0220 g.	2nd "
6/8/46	3.0468 g.	2nd "
20/8/46	3.3484 g.	2nd "
29/8/46	3.5882 g.	2nd "

It was therefore concluded that there had been a great improvement in the liver function during this period.

Attempts were also made to raise the low plasma protein level by repeated plasma transfusions, high protein diet, and the addition of "casydrol" by mouth. Plasma protein estimations were as follows: July 2, 1946, 5.1 g. %; July 12, 5.6 g. %; July 15, 5.4 g. %; July 19, 5.5 g. %; July 29, 6.2 g. %; Aug. 6, 6.2 g. %; Aug. 20, 6.8 g. %; Sept. 2, 6.85 g. %; Oct. 1, 1947, 7.8 g. %; Jan. 1, 1948, 8.8 g. %—i.e., 5.2 g. of albumin per 100 ml. of serum and 3.6 g. of globulin per 100 ml. of serum (albumin-globulin ratio = 1:1.5); March 9, 1948, 6.25 g. %—i.e., 4.5 g. of albumin per 100 ml. of serum and 1.75 g. of globulin per 100 ml. of serum—albumin-globulin ratio = 2.6:1. It was, however, noticed that although the plasma protein level was 6.8 g. by Aug. 20, 1946, the ascites persisted.

The patient felt very much better, and it was then decided to try to keep the white blood cells within reasonable limits by the administration of urethane by mouth. He was given 1 g. daily for four weeks and the white blood count was recorded daily. After that he was placed on a maintenance dose of 1 g. thrice weekly and weekly blood counts were recorded.

The remarkable fact was that the ascites after tapping took much longer to recur, and when he was tapped on Nov. 12, 1946, 24 pints (13.6 litres) of ascitic fluid were removed. Since that date he has been receiving two "fersolate" tablets three times daily, 1 g. of choline chloride daily, 1 g. of cystine daily, and 1 g. of urethane thrice weekly, with occasional rest periods as determined by blood counts.

He was seen again on March 31, 1948, when he was admitted to hospital for another paracentesis—i.e., after an interval of 16 months. Fourteen pints (7.95 litres) were removed on this occasion, and he remained free from signs and symptoms of ascites until Sept. 4, when he was last seen. His liver was just palpable at the costal margin, whilst his spleen extended only a hand's breadth below the left costal margin. His weight has remained fairly stationary in spite of his excellent appetite, and he feels very fit though his haemoglobin is low.

Since May, 1948, I have administered, in addition to the other medicines, 4 ml. of "anahaemin" intramuscularly at weekly intervals in an attempt to raise the haemoglobin and red blood cells, but so far without success. It has also been necessary to administer the urethane in doses of 1 g. daily to keep the white blood count within reasonable limits.

Discussion

This case is most interesting because when the patient was first seen in April, 1946, it was thought that he would live only a few weeks. The remarkable change which took place in his general condition after the administration of the

cystine and choline chloride was astonishing. His plasma protein rose fairly rapidly, the ascites became less pronounced and required less frequent tapping, his liver became normal in size, and he rapidly put on weight. After the addition of urethane his white blood count was kept within reasonable limits and his spleen rapidly diminished in size.

It is impossible to draw any conclusions from only one case, but I consider that there is a very fruitful field for the treatment of such cases with cystine and choline chloride in combination with urethane.

As pointed out by Cheney (1934), the presence of ascites in cases of chronic myeloid leukaemia seems to be rare, and very few cases have been recorded in the literature. He gives a detailed description of two such cases, and mentions the close resemblance of this condition to Banti's disease. The importance of making a correct diagnosis is stressed, as also is the institution of the appropriate treatment. He considers that the only probable causes of the ascites in these cases are portal thrombosis and low colloidal osmotic pressure of the blood plasma.

I would like to express my deep appreciation to Dr. F. Young for her invaluable help in the pathological investigations in connexion with this case.

Oxford

AND

JOHN A. SHEPHERD, M.D., F.R.C.S.Ed.

Lecturer in Surgery and First Assistant, Department of Surgery,
University of Liverpool

A case is described in which an unusual complication developed during or after labour, giving rise to an acute abdominal condition. A rupture of the liver associated with haemoperitoneum was found at operation.

Case History

The patient, a 6-para aged 32, was admitted on Sept. 11, 1948, 17 hours after parturition, with severe upper abdominal pain. The onset was sudden, occurring one hour after expulsion of the placenta and after the midwife had left the house. The patient became collapsed and vomited several times. She described the pain as sharp, radiating to the back and right shoulder, and increasing in severity on movement and respiration. All six previous pregnancies and labours were normal. During the last month of the present pregnancy she had suffered from a persistent epigastric pain.

On examination the patient was pallid and weak and was prevented by the pain from moving in bed or sitting up. The temperature was 97° F. (36.1° C.), pulse 112, and blood pressure 110/85. There was generalized abdominal tenderness and guarding, and shifting dullness was detected. The liver was palpable and tender, projecting 1½ in. (3.75 cm.) below the right costal margin. Peristaltic sounds were active. The pelvic organs were normal, although considerable peritoneal tenderness was elicited by palpation of the lateral fornices. The haemoglobin was 51%. A catheter specimen of urine contained 100 mg. of protein per 100 ml.

Since the precise diagnosis was undetermined, it was decided to transfuse the patient with 4 pints (2.27 litres) of blood and keep her under close observation. Heroin in small doses was given periodically.

During the subsequent eight hours the pulse rate rose slowly to 120 and the blood pressure to 150/100. No further vomiting occurred, but as peristaltic sounds had almost ceased and the abdomen had become distended it was decided to perform a laparotomy. An intraperitoneal haemorrhage, with a large effusion of blood below the right diaphragm, was suspected.

Operation.—A right paramedian incision extending well above and below the umbilicus was made. The peritoneal cavity was full of fresh blood. The spleen and uterus were normal and the gut was distended. A large clot was found obscuring the surface of the liver; when this was removed a subcapsular haematoma was observed to extend over the superior surface of the right lobe. The left lobe was normal. The peritoneal coat had been stripped up, and there was a rent in it through which blood was oozing. The clots and free blood from the peritoneal cavity were removed, and "oxycel" gauze controlled the haemorrhage from the raw area of the liver. A biopsy of the liver was taken at the margin of the haemorrhagic area. The liver area was drained and the abdominal wall closed in three layers. A Ryle's tube which had been introduced before operation was kept *in situ*.

Progress.—The condition of the patient improved perceptibly; within 24 hours the pulse rate dropped to 100 and abdominal distension disappeared with the recurrence of peristalsis and the passing of flatus. Gastric aspiration was continued for 36 hours, after which the patient was able to take a light diet. Penicillin, 100,000 units at first, decreasing to 40,000 units, was given three-hourly for 15 days. The patient remained pyrexial for 25 days.

On the 24th day there was clinical evidence of right basal pulmonary collapse with pleural effusion. On the 34th day she developed a sharp attack of pleural pain associated with a swinging temperature of 102–98° F. (38.9–36.7° C.). A further course of parenteral penicillin was given, 60,000 units three-hourly and, later, 200,000 units twice daily, with penicillin inhalations for 18 days. Temperature and pulse rate became normal on the 43rd day. A pleural aspiration was carried out on the 39th day: the fluid so obtained was sterile.

On Nov. 11 (64th day) the patient was discharged from hospital. The blood pressure was 130/90. There was no albuminuria. Evidence of pleural effusion was still present, but her general condition appeared satisfactory.

Investigations.—The Wassermann reaction and Kahn test were negative; haemoglobin was 51%; and white blood cells numbered 22,000. A catheter specimen of urine contained 100 mg. of protein per 100 ml. The blood pressure was 114/85 to 155/100. The blood urea amounted to 124 mg. per 100 ml., the plasma bilirubin to 2 mg. per 100 ml.; and total proteins to 5.3 g. per 100 ml. (albumin, 3.1 g.; globulin, 2.01 g.; fibrinogen, 0.69 g.). A high vaginal swab produced no pathogenic organisms. An x-ray film of the chest showed the right diaphragm raised, with collapse of the base of the right lung and effusion, and, several days later, collapse of the middle lobe with effusion. Liver biopsy showed zonal necrosis with some cellular infiltration—an appearance compatible with that found in toxæmia.

On discharge the haemoglobin was 84%, and the white blood cells numbered 8,000. A catheter specimen of urine contained 100 mg. of protein. The blood pressure was 130/90. An x-ray film of the chest showed some improvement in the extent of effusion and pulmonary collapse. The E.S.R. was 33 mm. per hour (Westergren).

Discussion

Rupture of the liver has been described either as traumatic or as "spontaneous" rupture. The first is a well-recognized condition due to direct injury, and discussion of it is irrelevant in this article. The second—the "spontaneous" rupture—is the type to which the present case belongs. In this type the trauma is either slight or has passed unrecognized by the patient. This use of the term "spontaneous" is unfortunate, and may be misleading when applied to liver rupture, as it certainly is when used to describe a splenic rupture attributed to minimal or unrecorded traumata.

Under the heading "ruptures spontanées" Devic and Bériel (1906) have discussed liver rupture and made particular reference to the pathological condition of the organ at the time of its rupture and to the possible association with syphilis. Of the 21 cases reviewed by them only one—Abercrombie's case, to which further reference will be made—was associated with pregnancy.

Devic and Bériel suggested that when definite trauma could be excluded the term "apoplexie hépatique" might be used. They expressed a clear opinion that in traumatic rupture it is the rupture which causes the haemorrhage, but that in spontaneous rupture the haemorrhage is the cause. The sequence of events leading to spontaneous rupture is, they suggest, as follows. Rupture of a blood vessel leads to intrahepatic haemorrhage; this in turn causes local laceration of liver tissue and the formation of a subcapsular haematoma; finally, the capsule of the liver may rupture and blood escape into the peritoneal cavity.

Such intrahepatic haemorrhage, they suggest, may be caused by a variety of conditions—for example, vascular disease, necrosis of the liver associated with septicaemia, or hepatic malignancy. In some cases minimal trauma may cause haemorrhage in diseased liver comparable with the haemorrhage that is known to occur in the diseased spleen.

Abercrombie's (1843–4) case, to which reference has already been made, was associated with pregnancy. He gives a vivid account of a woman aged 35 who suffered from epigastric pain, abdominal distension, and belching at the eighth month of pregnancy. He says of the patient: "Having had frequent attacks of gastrodynia on former occasions, she, of her own accord, had immediate recourse to pressure for relief; and placing a silk handkerchief round her body she desired one of her servants to pull it as tight as she possibly could. The wish was complied with, but to an extent that made me fear some injury under existing circumstances. I therefore begged it might be removed. I then prescribed for her a draught composed of Calceined Magnesia, Liquor Opii Sedativus, Spt. Ether., Sulph., and Aq. Cinnamonomi, to be taken immediately, and ordered hot fomentations to the epigastrium. By these means the pain gradually abated." A few hours later labour began and was soon followed by the successful breech delivery of the foetus. An hour after the expulsion of the placenta the patient collapsed. Haemorrhage was suspected, but there was no evidence of its coming from the birth canal. Two days later the patient died, and a post-mortem examination revealed a large unruptured subcapsular haematoma on the superior and anterior surfaces of the liver.

Abercrombie was of the opinion that the damage to the liver might have been caused by the tight bandaging, but that haemorrhage did not occur until the pressure of the gravid uterus on the upper abdomen had been removed. He also put forward an alternative suggestion that haemorrhage took place in a liver that was already so diseased that it was readily injured by the muscular compressions of labour.

Alessandri (quoted by Rademaker, 1943), writing on this subject, agrees that rupture of the liver may occur as the result of violent muscular activity during parturition or during epileptic seizures, but he gives no case report or reference to support his views.

Rademaker (1943) describes the case of a woman aged 32 admitted to hospital in the eighth month of pregnancy with a blood pressure of 260/160 and albuminuria. After a severe bout of vomiting she became collapsed and the diagnosis of a ruptured uterus was made. At operation a rupture of the liver (the exact site is not specified), with blood in the peritoneal cavity, was found. The haemor-

rhage was controlled by a pack, and after a stormy convalescence the patient recovered. In this case hypertension was thought to be the cause.

Rademaker submits the interesting suggestion that sudden death during eclampsia may sometimes be due to a ruptured liver. We doubt, however, whether this speculation can be sustained, for, although scattered areas of necrosis and small subcapsular haemorrhages are not infrequently found in eclampsia, severe haemorrhages of the liver are not a feature of this disease.

Links (1946) describes a case of rupture of the liver during the fourth month of pregnancy. The patient developed acute abdominal pain with signs of blood in the peritoneal cavity. At operation the blood was found to be coming from the foramen of Winslow. On exploring the lesser sac a laceration of the caudate lobe of the liver was seen; the liver tissue itself appeared to be normal. Haemostasis was effected by covering the site of bleeding with muscle tissue. The patient made a good recovery. The cause of the liver damage was obscure, but Links suggests that it may have been due to a transient hypertension.

Conclusion

We have been able to trace three cases of ruptured liver associated with pregnancy, two of which survived as the result of operative intervention. To these three cases we have added a fourth, in which also the patient recovered after surgical treatment.

We believe that in our case the injury was the result of trauma produced by violent contraction of the diaphragm and abdominal muscles during labour. But it is interesting to note that there was also an element of toxæmia, evidenced by the raised blood pressure (found after the initial shock had been overcome) and by the presence of albuminuria. It is probable that this toxæmia produced changes in the liver, making it particularly liable to injury. (The complaint of epigastric pain for one month before parturition and the report on the liver biopsy obtained at the time of operation strengthened this suggestion.) There was, in our case, no evidence of syphilis or other constitutional disease.

Regarding operative treatment, we believe that the application of "oxycel" gauze, fibrin foam, or muscle tissue is preferable to suture. It is also obvious that blood transfusion is an indispensable part of the treatment. Our patient's satisfactory recovery bears out the statement of Rademaker that in cases of liver rupture operation affords a good chance, and probably the only chance, of survival.

Summary

A case is reported of rupture of the liver, with haemoperitoneum, occurring in association with parturition. Only one comparable case has been found in the literature.

The immediate cause of the rupture was probably the muscular compression that occurs with the expulsive efforts of labour. A predisposing factor may have been the presence of liver damage brought about by pregnancy toxæmia.

The use of the term "spontaneous" rupture is deplored. Liver ruptures may be divided into two main groups: traumatic rupture and hepatic apoplexy—the first usually affecting a healthy liver and the second occurring because of haemorrhage in a pathological liver. A subgroup may be added in which minimal trauma causes rupture of a pathological organ. The case reported may be regarded as an example of this subgroup. This classification of liver rupture might usefully be applied to ruptures of the spleen.

Treatment of a Chronic Typhoid Carrier with Chloromycetin

Good clinical reports upon the use of chloromycetin in the treatment of typhoid fever have naturally aroused interest in the possibility of dealing with the chronic typhoid carrier by similar means. Unfortunately there is no literature available on the efficacy of this form of treatment; nevertheless as a suitable case had recently come under our care it was decided to try the effect of the substance in doses which had been successful in dealing with the acute disease.

CASE REPORT

A child aged 9 years, son of a flight sergeant in the Royal Air Force, contracted typhoid fever in Egypt in June, 1948, from which he made a good clinical recovery, though he was left a chronic faecal carrier. He came under our care in the spring of this year. He was a well-nourished healthy-looking boy. His stools consistently yielded a heavy growth of *Salmonella typhi*, though over 40 specimens of urine were sterile. *In vitro* sensitivity tests with the isolated organism showed it to be very susceptible to traces of chloromycetin: dilutions in excess of 2.5 µg. per ml. inhibited bacterial growth. It was decided to follow a therapeutic course which had been successful in treatment of the acute disease in the adult, using 19.1 g. of chloromycetin in 8.1 days. As the child weighed 4 st. 7 lb. (28.5 kg.) it seemed appropriate to give half the adult dose, which was administered orally in 0.25-g. capsules four-hourly day and night for seven days—a total of 10.5 g. Stools were cultured on alternate days while undergoing treatment, and we were disappointed to find the organism present in all of them: failure was evident before treatment was completed. In view of this finding, a second course, using three times the dose, was instituted—viz., 0.75 g. for seven days (total, 32.25 g.). Stools became negative almost immediately after starting treatment and remained negative until two days after withdrawing treatment, after which he continued to excrete the organism daily in his stools.

While undergoing the course of treatment his blood serum inhibited growth of the isolated organism in dilutions rising from 1 in 2 on the first day to 1 in 32 by the third day. This inhibition of growth disappeared 16 hours after the last dose of chloromycetin was given.

COMMENT

Chloromycetin in doses of 30 mg. per kg. of body weight for seven days has failed to eliminate the organism in a chronic faecal typhoid carrier. This dose is about three times that which has been successful in treatment of the acute disease. The cause of the failure is not clear, especially in view of the marked sensitivity of the organism to chloromycetin *in vitro*. It is possible that much heavier doses for longer periods are advisable. Further clinical trials are necessary before any conclusions can be drawn regarding the efficacy of the substance in treating the chronic faecal carrier.

In a referendum the Swiss electorate has rejected by a proportionate majority of three to one a controversial law to make x-ray examinations and tuberculosis treatment compulsory. The draft law (according to a B.U.P. report) provided for the periodic examination of the population for tuberculous infection, for the compulsory insurance of the poorer classes against the economic effects of tuberculosis, and for removal to an isolation hospital of sufferers who might endanger others. The law would have been costly: besides its insurance provisions, of which part of the cost would have been borne by the Government and employers, the law required the cantons to contribute to the support of poor families when the wage-earner was suffering from tuberculosis and to pay the costs of x-rays when the family concerned had too low an income to afford them. There would also have been the difficulty that many Swiss peasants have never been, and do not want to be, treated by a doctor. A number of Swiss doctors also criticized the draft law, pointing out that people can hardly be compelled to undergo examination and treatment when there is no acknowledged method of either.

Reviews

PROTOZOAN DISEASES

Laboratory Diagnosis of Protozoan Diseases. By Charles Franklin Craig, M.D., F.A.C.S., F.A.C.P. Second edition. (Pp. 384; 56 illustrations and 7 coloured plates. £1 7s. 6d.) London: Henry Kimpton. 1948.

There are few, if any, workers in the United States who have contributed more to the study of amoebiasis than Colonel Craig, and his chapters devoted to this subject constitute one of the best expositions on the laboratory (and certain clinical) aspects of the condition that can be found in the literature. Over one-third of his book is devoted to this subject, which is considered in seven chapters.

The author gives descriptions of over a dozen methods of cultivating amoebae, but very wisely warns the reader that he should concentrate on one technique, and without dogmatism gives an indication of the methods he prefers.

Not long ago an ex-Service contributor of an article on amoebiasis in the *Journal* mentioned that he believed there was a complement-fixation test for amoebiasis. If he reads this book he will see how right he was. Colonel Craig first published the results of his observations on this subject in 1927, and he gives 16 references to other workers up to 1946. Nevertheless, although the test has come of age, it has not, in the reviewer's opinion, reached stabilized maturity. It would be hard to say that it has yet earned a place in the diagnosis of amoebiasis, though Colonel Craig considers that it has. Anyone who proposes to take up work in this line—and there is obviously still room for it—must certainly study this chapter very carefully. The only criticism is that the wartime work at the National Institute of Health has not been given the prominence that it deserves.

There can be no question that a reliable standardized complement-fixation test would be of very great value in this country to-day. During the war hundreds of thousands of our troops were infected with amoebiasis in the India-Burma area; liver abscess is a not uncommon late sequel to this infection; and when this condition is suspected a stool examination is of little value one way or the other. In over 60% of cases amoebae are not found, and when they are found their presence may be incidental. Colonel Craig emphasizes this reason and gives many others—to all of which the reviewer cannot subscribe—for the wider employment of this test.

The other subjects covered are: the leishmaniasis, the trypanosomiasis, malaria, coccidiosis, and balantidiasis. The author's close contact with South America and South American workers has given him opportunities of which he has taken full advantage in the sections on Chagas's disease, and there is much more information on this subject than is found in most other textbooks on protozoal diseases. The other chapters are useful but not distinguished. It is a useful laboratory textbook for reference purposes.

L. E. N.

DICTIONARY OF GENETICS

Dictionary of Genetics. Including Terms used in Cytology, Animal Breeding and Evolution. Compiled by R. L. Knight, D.Sc., Ph.D., A.I.C.T.A. (Pp. 183. \$4.50.) Waltham, Mass., U.S.A.: Chronica Botanica Company. London: William Dawson and Sons. 1948.

Genetics in its earlier years was a highly specialized branch of biology and to a large extent remains so to-day. Its students made up their technical vocabulary as they went along. Sometimes the result was reasonably felicitous, though by no means always: "non-disjunction" stands for a hallowed landmark in the development of the subject, but remains a horrid word. But whether the results were happy or unhappy, the new terms have always been a stumbling-block to those outside the field of genetics, and even geneticists have to pause at times in order to make sure of precise meanings. Different terms have sometimes been coined to describe the same thing, and occasionally a word has been used with different meanings. In short, there is probably no specialty in biology which has

so urgently demanded a dictionary. That dictionary has now been produced, and an admirable volume it is. It is complete—few genetic terms indeed can have escaped definition; the definitions are brief and lucid; there is ample use of cross references. Dr. Knight has produced a volume which, with slight revision in subsequent editions, should remain a standard work for many years to come. It should be included in every biological library.

Dr. Knight has, probably wisely, not felt that it is any part of his task to be critical. He accepts the words in use, or which were previously in use, and defines them all. One hopes however, that in the second edition, perhaps after studying the reactions of geneticists to the first, Dr. Knight may be able to guide his readers to the better use of words. He may indicate for example, that certain alternatives are to be preferred to others, or that certain terms are unnecessary and should not be employed. I have detected only one downright mistake. It is a pity that Dr. Knight gives the sanction of his dictionary to the word "expressivity." The correct word is "expressiveness"—the only form given in the *Oxford Dictionary*. Similarly, the *Oxford Dictionary* gives "recessiveness" and not "recessivity," though Dr. Knight, less than complete for once, does not give either.

There are a few brief appendices. One, on the international rules for symbolizing genes and chromosome aberrations, is particularly useful. A number of statistical formulae are also included. It is perhaps helpful to have the more purely genetic of these in this volume, but one questions the necessity of including such familiar formulae as those for the correlation coefficient or the standard deviation, given, at that, in a form inconvenient for practical computation. This is a trivial point however, and this book can be recommended very warmly indeed.

J. A. FRASER ROBERTS.

NEUROPATHOLOGY FOR STUDENTS

Atlas of Neuropathology. By Wm. Blackwood, M.B., F.R.C.S.Ed., T. C. Dodds, F.I.M.L.T., F.I.B.P., F.R.P.S., and J. C. Sommerville, A.I.M.L.T. With foreword by Professor A. Murray Drennan, M.D., F.R.C.P.Ed., F.R.S.Ed. (Pp. 199; 262 illustrations. 35s.) Edinburgh: E. and S. Livingstone. 1949.

Expositions of pathology in atlas form appear popular to-day. In no branch is such presentation better justified than in the student's point of view than in neuropathology, because fixation of the brain in bulk is usually essential for a satisfactory demonstration of most lesions. But the brain thus becomes divorced from the rest of the necropsy findings, to the detriment of teaching. The atlas carries the additional advantage of being a method for bringing microscopical demonstration into conjunction with the naked-eye appearances. In the present work Dr. Blackwood has enjoyed the expert technical help of Mr. Sommerville and the photographic skill of M. Dodds. The result is a satisfying display of most of the commoner pathological conditions in the nervous system. Many of the most successful illustrations are in colour, as are of these the examples of meningitis are specially commendable as life-like representations. In addition to photographs a considerable number of explanatory diagrams have been included.

The general arrangement of the subject matter follows that of Professor J. H. Biggart's *Pathology of the Nervous System*, which, as one of the shorter treatises on this subject is unsurpassed. The student is recommended to use this one of the fuller texts in conjunction with the atlas, since Dr. Blackwood's supplementary notes are in most instances brief. This advice is given in the preface.

DOROTHY S. RUSSELL.

PATHOLOGY FOR STUDENTS

Essentials of Pathology. By Lawrence W. Smith, M.D., F.C.A.P., and Edwin S. Gault, M.D., F.C.A.P. With foreword by the late James Ewing, M.D. Third edition. (Pp. 764; 740 illustrations. \$12.00.) Philadelphia and Toronto: The Blakiston Company, 1012 Walnut Street, Philadelphia. 1948.

The first edition of this book was to a large extent an experiment. To quote the foreword, written by James Ewing, it was a serious attempt "to take the teaching of pathology out

the realm of abstract philosophy and make it an effective force in the professional equipment of the medical student." The method employed was to illustrate the basic text, which was that of a standard textbook, with carefully selected case-histories, complete with histological, clinical and x-ray photographs. Almost every illustration in the book was therefore related not only to the text but to a clinical account of an actual case. The business of correlating the academic pathology of the textbook with clinical observation is for the most part left to the student himself, and this book was the first serious attempt to help him materially in this most difficult task.

The second edition was considerably expanded to deal fully with the principles of general pathology. This greatly added to the value of the book. The number of case reports was reduced by omitting those in which most of the clinical detail was irrelevant to the pathological condition under discussion.

In this, the third edition, the case-history method of teaching has been preserved and the book has lost none of its individuality. Many illustrations have been replaced and sixty-one new ones added, and wherever feasible the case-histories have been condensed. There has been some judicious pruning, and the page size, weight, and number of pages have been reduced. This book will be read with interest and profit by both junior and senior students.

GEOFFREY HADFIELD.

ESSAYS ON ANAESTHESIA

Anaesthesia for the Poor Risk, and Other Essays. By William W. Mushin, M.A., M.B., B.S., F.F.A.R.C.S., D.A. Being included as No. 49 in the American Lecture Series. (Pp. 65. 7s. 6d.) Oxford: Blackwell Scientific Publications. 1949.

In these days of hurry and bustle it is refreshing to note that someone has had time to write a book of essays on a medical subject. The author is to be congratulated on having had the time and ability to sit back and survey the field on anaesthesia from a detached and objective viewpoint. Nowadays it is all too easy for the busy anaesthetist to be so preoccupied with the details of complicated techniques which may be essential to cope with the demands of difficult operations that he loses his sense of proportion and cannot see the wood for the trees. It is salutary to escape for a time from the cramping effects of individual problems and to gaze on the wider aspects of modern anaesthetic practice and teaching.

Dr. Mushin does this in twenty-eight short essays which can be read through at one sitting. The title of the book refers only to the first essay and is thus somewhat misleading. Actually, an immense range of subjects is discussed, and while some readers may not always agree with the author's views on certain controversial matters they will enjoy his method of "debunking" many popular fallacies held not only by some anaesthetists but also by not a few of the less progressive physicians and surgeons.

C. LANGTON HEWER.

Professor E. F. Du Bois in his *Fever and the Regulation of Body Temperature* (pp. 68; 10s. 6d.; Springfield, Illinois: Charles C. Thomas: Oxford: Blackwell Scientific Publications, 1948) gives an excellent survey of the field while sparing the reader the confusion and detail which abound in the voluminous literature relating to thermal regulation. As a professor of physiology, a notable experimenter, and an authority on the topic, Du Bois is well fitted to present this American lecture in physiology. It should be equally appreciated by the student freshly introduced to this subject and the graduate interested in the question of body temperature. The author presents the difficulty of comprehending a "normal" body temperature, with its extensive gradients and fluctuations. The relation between heat production and heat loss with varying environmental temperatures is analysed to show the relative parts played by radiation, convection, and vaporization. The normal balance is compared with that in exercise and in disease, with special reference to the skin, clothing, chills, and tissue metabolism. As one would expect, clinical aspects are not stressed; but clinical details are used for illustration and mention in connexion with fever, fever therapy, cold therapy, and the management of febrile patients. The lecture is short and easy to read, with helpful diagrams and adequate references to original works of significance. "There is much to be learned about fever," but this is an interesting and stimulating précis of what is known.

TUBERCULOSIS IN INDUSTRY

Many of the theories put forward to explain the prevalence of tuberculosis in certain industries are accepted as facts on insufficient evidence. For instance, it is commonly believed that the tuberculous person must be provided with open-air employment, but the experience gained at Papworth Settlement and the British Legion Village at Preston Hall has shown that such conditions of employment are not only unnecessary but are often harmful owing to the strenuous nature of the work and poor working conditions, including exposure to all kinds of weather. Certain trades, too, have been condemned as being unsuitable for the tuberculous on the grounds that there is a high mortality from tuberculosis among the workers. The few studies made on this problem have shown that an increased incidence of tuberculosis among employees often has little connexion with the manufacturing process but is mainly due to domiciliary and industrial environment. A good example of such a trade is that of printing, which when carried out under proper conditions, as found in the workshops of industrial settlements, is one of the most suitable occupations a tuberculous person can follow.

The high death rate from tuberculosis among workers in the boot and shoe industry has been known for over 50 years. The Medical Research Committee (forerunner of the Medical Research Council) published a report¹ on the subject in 1915, but beyond confirming that there was more pulmonary tuberculosis among workers in this industry than in the general population they were able to put forward only conjectures about the cause. In 1947 Smith² published the findings of the mass-radiography survey in Northamptonshire, and again the statistical evidence showed that there was a higher proportion of workers with active tuberculosis in the boot and shoe industry than in other industries in the county. The report by Drs. Alice Stewart and J. P. W. Hughes which appears elsewhere in this issue is a direct outcome of the mass-radiography survey—the work having been undertaken at the request of the industry.

Drs. Stewart and Hughes first turned their attention to proving or disproving two of the commonly accepted opinions about the workers in the boot and shoe industry—that many men of poor physique are employed, and that there is a strong family tradition in the industry, with the result that two or more members of a family are often

employed in the same factory. These terms indeed can be brief and lucid. Dr. Knight has produced in subsequent editions, and that there was some indication. makers are more often interrelated. He accepts the workers in the area and are more frequent, and defines the tuberculous infection in their homes.

The next step in the investigation was to find out, Dr. Knight infection was spread in the factories, and, if so, how it spread. The incidence of tuberculosis in those factories of different sizes was studied, and it was found that the overall rate of infection was considerably higher in large factories than in small ones. Having satisfied themselves that the difference was not due to the large factories employing workers whose age and sex constitution differed from those in small factories, Drs. Stewart and Hughes then compared the working conditions in the large and small factories from reports supplied by factory inspectors. The information obtained was valuable. 24% of the factories with fewer than 200 operatives the working conditions were not altogether satisfactory, whereas in all the factories with more than 600 operatives the working conditions were well above the average standard. But the study of the results obtained in the mass-radiography survey showed that the incidence of tuberculosis was over four times as great in the large factories with "good" conditions of work as in the small factories where the conditions were not so good.

In a large community more people are at risk than in a small community, and Drs. Stewart and Hughes's investigation of the factories according to the number of operatives per room suggests a probable explanation for the difference in the incidence of tuberculosis in large and small factories. All the large factories had more than 60 operatives per room, and 80% of the small factories had fewer than 20 per room. Drs. Stewart and Hughes are careful to state that further work will have to be done before they can be certain that the size of the working unit is the core of the problem. It is clear, however, that workers with active tuberculosis could cause much harm among the young employees from rural areas who are non-infected when they take up work, especially if resistance to infection is lowered by unsatisfactory nutrition, over-fatigue from long journeys to and from work, and poor living conditions. In fact, infectious persons working in a room with 60 or more employees may be the cause of local epidemics of tuberculosis. Such an epidemic in a school in Copenhagen was reported by Hyge³ in 1947 and referred to in an annotation in the *Journal*⁴ some months ago.

The boot and shoe industry is to be congratulated on its admirable collaboration in this important pioneer research. The report now published is a preliminary one and is concerned with conditions in only part of one industry; from the evidence so far collected it would be unreasonable to deduce that in the shoe industry the incidence of tuberculosis is greatly different from that in many other industries. For all we know, similar working conditions in other industries are as likely to favour the spread of tuberculosis among the workers. Surveys carried out at Uxbridge,⁵ Oxford,⁶ and Hull⁷ have shown that considerable numbers

THE SE VOLUNTARY ACTION IN WAR

With the British Red Cross Society and Order of St. John of the salem are to be congratulated on the prompt appearance of the official history of their Joint War Organization.¹ It is a document of more than passing interest, for it illustrates on a gigantic scale the nature of the problems which arise in the integration of voluntary and governmental activities in conditions of emergency. The initial aim of the "Red Cross movement"—embodied in the first Convention of 1864—was to ameliorate the conditions of the wounded and sick in armies in the field. Other objects, added later and without weakening the primary purpose, have included the care of prisoners in time of war, the improvement of health, the prevention of disease, and the mitigation of suffering. The Red Cross and St. John organizations in this country became the national representatives of a movement which in its ideals is supranational and in privileges international—with the notable exception of Japan in the last war.

Inevitably the first impression gained from this record is the size of what was done. The Joint War Organization began the war with a fund of £2,000, contributed equally by its parent bodies. It ended with an expenditure of £64 millions—the largest charitable fund ever collected in Great Britain. Of this enormous sum, over £20 millions came from penny-a-week collections, which from January, 1944, onwards were yielding £500,000 or more per month. On the disbursement side, £51 millions was spent on current war services during the lifetime of the organization, and the balance of £12½ millions was handed over to the parent bodies for expenditure over a longer period for purposes permitted by the War Organization. A rough indication of the scope of the different services provided can be obtained from the outlay on them. Services for the wounded and sick of British and Empire Forces absorbed £17 millions; for British and Empire prisoners of war, £14 millions; for Allied Forces, £5 millions; and for civilian relief overseas, £13 millions.

The record neither conceals nor over-emphasizes the difficulties which arose. It was a general and logical policy that, whereas it was for the Service and civilian departments to provide for basic needs, it was the business of the War Organization to supplement. In addition to comforts, this included on the hospital side "additional stores . . . ambulances, x-ray apparatus, and the like . . . convalescent hospitals for officers, and convalescent homes and auxiliary hospitals for other ranks." From the nature of this specification it can be judged that there was often considerable uncertainty about the extent of the task confronting

the War Organization. For example, by March, 1940, the War Organization had 20 ambulances in France—the intention being that Army ambulances should be relieved for work in the forward areas. By the middle of May the D.M.S. was pressing the Commission in France for further ambulances; but when the existing vehicles were abandoned and their personnel evacuated in the following months the negotiations with the War Office, which were begun in the preceding November, were still not concluded. In June of the same year—the time of Dunkirk—an offer of 100 ambulances was made and accepted for service with the Home Forces, and by December, 1941, the total was 239. In the evidently delicate matter of supplies to Service hospitals it took some months before "the happy medium" was reached. This was an arrangement by which a D.D.M.S. might forward indents directly to the War Organization and which officially encouraged liaison with "Red Cross" officers in Commands. It was at first thought that motor x-ray units would not be required: later a request was made for 20.

In the provision of additional hospital and convalescent facilities there was a precedent from the 1914-18 war, when "an extensive system of auxiliary hospitals . . . for officers and other ranks" was established. It was at first suggested that convalescent homes for officers would be all that was needed, and that six with about 100 beds each would be sufficient. In March, 1940, it was stated on behalf of the Ministry of Health that the War Organization would probably not be asked to establish auxiliary hospitals. Later the War Organization was asked to "obtain, adapt, and equip suitable buildings as convalescent homes for other ranks," with a target first of 10,000 beds, then 20,000. Later still it appeared that "as between auxiliary hospitals and convalescent homes there would be little or no difference of staffing and equipment"—due, in part, to great emphasis on rehabilitation. The directory of convalescent homes and auxiliary hospitals, as finally established, runs to six closely written pages in an appendix to this volume. The number of beds equipped reached 14,000, that of beds occupied just over 8,000—a by no means insignificant addition to total hospital services.

The failure of the Japanese Government to abide by its undertaking to observe the provisions of the Prisoners of War Convention—which, however, it had never ratified—was the outstanding and tragic feature of the prisoner-of-war services. In the "occupied territories" the Japanese High Command was "the sole unquestionable authority." This explanation cannot, however, be invoked in the case of Japan itself. Notification of camps was not made to the delegates of the International Red Cross Committee; and, where only forty-two prisoner-of-war camps had been known, there were found after the surrender to be more than one hundred. Similarly, "information about the receipt of relief came almost wholly from prisoners themselves after their liberation": there were no camps where more than irregular, and even solitary, issues had been made, but when concealment was no longer possible "quantities of relief supplies were brought to light."

Other services can be mentioned only briefly. Those for British civilians raised a number of problems without precedent. In this category were members of the Forces

dissimilar contemporaries." On the other side Professor R. B. Onians⁶ pointed out that fees provide a very small part, and endowments and public funds a very large part, of the capital value and running costs of a university, and "justice and the national interest demand that university education be given to those who bring to the university not mere fees but gifts of mind and personality most worthy of development." Professor J. D. Bernal⁷ gave it as his opinion that the policy of providing university education for all students who can profit by it will not lead to a lowering of the standard of entrance, and he stated that even with the post-war expansion barely one child in 40 in this country has a chance of university education. "This," he writes, "is one of the lowest proportions in Europe, and a quarter of what it is in the U.S.A."

One method of easing the pressure on the universities was mentioned in the *Journal* recently by Professor L. J. Witts⁸ in a review of a book entitled *The Problem Facing British Universities*. The need for more scientists might be met by a more ruthless separation of university and technical education and the creation of more technical colleges. So far as medical students are concerned he suggests that the Oxford and Cambridge practice of preclinical education within the university followed by clinical work in autonomous teaching hospitals may become the pattern for medical education in Britain.

ACUTE INFECTIVE POLYNEURITIS

The cause of acute infective polyneuritis is still unknown, but the signs on which to make a diagnosis are reasonably clear. A mild upper respiratory infection often precedes the onset of the neurological disease. There is a fairly rapid development of symmetrical flaccid paresis, usually starting in the legs and ascending to the trunk and arms, and often accompanied by considerable muscle pain and paraesthesiae. In some cases the paralysis affects the proximal more than the distal muscles of the limbs. Sense of position and stereognosis are frequently more severely disturbed than is cutaneous sensation, though some diminution of sensation over the glove-and-stocking areas can usually be demonstrated. Bilateral facial weakness occurs in a number of cases, but involvement of other cranial nerves, causing palatal and pharyngeal weakness and external ophthalmoplegia, is much rarer. In the majority of cases neurological disability reaches its maximum in two to three weeks or less, and gradual improvement then takes place, with eventual complete recovery.

One of the problems connected with this disease is its nomenclature: a recent review¹ mentions 30 different names which have been given to it. In France and to some extent in the United States the eponym Guillain-Barré syndrome is used, since these authors² in 1916 described two cases, stressed the good prognosis, and drew attention to the finding of a high protein content in the cerebrospinal fluid without any increase of cells. Clinical descriptions had been published previously,^{3,4,5} but the cerebrospinal fluid findings were not reported. Detailed case histories appeared in British journals in 1917⁶ and 1918.⁷ The stress which some authors have laid on the

albumino-cytological dissociation in the cerebrospinal fluid as a diagnostic point is not justified; in Bradford's⁷ cases, which were clinically similar to those of Guillain and Barré, the protein content was normal, while in such conditions as diabetic and diphtheritic neuritis the C.S.F. protein may be raised.^{8,9,10} It is possible, though not yet proved, that the raised protein indicates involvement of spinal roots; it is certainly not indicative of any particular reason for such involvement.

Histological investigations have revealed changes in the anterior horn cells¹¹ in addition to degeneration in spinal roots and peripheral nerves, and for this reason the term "neuronitis" has been used to describe the disease. No infective agent has yet been demonstrated. Guillain and Barré's views on the invariably good prognosis have not been confirmed, since a proportion of patients die of respiratory paralysis in the acute stage, while in a small number the disease becomes chronic, with long-standing muscle-wasting and weakness. Children are occasionally affected,¹² and in them the prognosis is said to be more favourable than in adults. Acute infective polyneuritis is the commonest cause of the syndrome to which the name Landry's ascending paralysis is sometimes given, though there is some reason¹³ to believe that Landry's original patient was suffering from the polyneuritis of acute beriberi, and other pathological conditions such as poliomyelitis and porphyria may cause the same symptoms.

CHLORAMPHENICOL (CHLOROMYCETIN) AND CHOLERA

Evidence is accumulating that chloramphenicol is of value in the treatment of typhoid. Woodward and his colleagues¹ have reported on its use in the Tropics, and Murgatroyd² has recently recorded in this *Journal* a case successfully treated with the new antibiotic in this country. Bradley³ also has given an encouraging preliminary account of its employment under controlled conditions in the epidemic at Crowthorne, in Berkshire. Elsewhere in this issue Rumball and Moore report their lack of success in the treatment with chloramphenicol of a chronic typhoid carrier. Gauld and his collaborators⁴ now bring forward evidence to show that chloramphenicol is active against cholera vibrios. Mice injected with cholera vibrios and given chloramphenicol by mouth within two hours of infection were practically all saved—only 3 died of the 120 mice so treated—whereas 25 of 60 mice treated with sulphadiazine succumbed, and 22 of 30 controls given no treatment at all. In the application of these findings to human cholera it must be recalled that it is not possible to reproduce the human disease in laboratory animals. Intraperitoneal injection of large doses of vibrios in mice causes peritonitis and septicaemia, but the vomiting, diarrhoea, and extreme dehydration characteristic of cholera in man are lacking. In human cholera the vomiting might make the administration of the drug by mouth impracticable and it might be necessary to give it parenterally. Indeed, it is probable that if chloramphenicol proves of use in the human disease its principal value may be as a prophylactic during epidemics. In the next outbreak of cholera chloramphenicol should certainly be given to exposed contacts in order to appraise its value for this purpose.

Professor Geoffrey Jefferson, F.R.S., will deliver the Lister Oration on "The Mind of Mechanical Man," before the Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., on Thursday, June 9, at 5 p.m.

RESEARCH ON VITAMIN E. INTERNATIONAL CONFERENCE

An International Conference on Vitamin E, organized by Professor K. E. Mason, was held recently at the New York Academy of Sciences. About 60 papers were contributed on the morphological lesions in vitamin-E deficiency, the part played by the vitamin in enzyme systems, its protective action under conditions of metabolic stress, its significance in practical nutrition, and its possible value in clinical medicine. While many interesting additions to our knowledge of the mode of action of the vitamin in experimental animals were presented, the conference remained undecided on the efficacy of vitamin-E therapy.

Enzyme Systems

It has long been known that when the muscles of vitamin-E deficient animals are incubated *in vitro* they respire more rapidly than tissues from normal animals. Hickman and others have held therefore that vitamin E has a general role as a "mentor" preventing oxidation in the tissues from proceeding through normal channels. Observations that α -tocopherol phosphate inhibits several enzyme systems might seem to support this view, but Ames and Risley have commented that the phosphate radical and not tocopherol may be responsible for the inhibition, while the detergent action of the compound introduces another complication. According to Miller and his colleagues, however, the succinate of tocopherol has the same effect as the phosphate in inhibiting hyaluronidase, while Zierler *et al.* found that tocopherol in the uncombined form inhibits trypsin. These workers noticed that rats given large doses of α -tocopheryl phosphate become drowsy within a few hours; when they were killed in this condition the rates of oxidation of the tissues *in vitro* were normally slow. Boyer agrees with the conclusion that the inhibitory action of α -tocopheryl phosphate on the succinyl dehydrogenase system of heart and liver is due to its detergent power, and has observed similar inhibition with dodecyl sulphate, a detergent bearing no chemical relation to vitamin E.

Experimental Animals

In middle-aged female rats Kaunitz and his colleagues found that the tendency of the oestrous cycle to lengthen from 4 days to as much as 17 days could often be corrected by giving tocopherol in amounts ten to twenty times greater than those required for young rats. The same treatment also improved the fertility rate, which decreased progressively with age in animals receiving normal amounts of the vitamin. On the other hand Telford found that deprivation of vitamin E decreased the incidence of artificially induced lung tumours. Evans affirmed that the muscular dystrophy caused by vitamin-E deficiency was accompanied by neural lesions, with demyelination of the spinal cord. In reaching the same conclusion Mason and his colleagues found that oxidized lard, although highly toxic to rats, was less effective than fresh lard in causing neural lesions. Lecoq and his colleagues found changes in the haematopoietic organs of deficient rats which may indicate a defence mechanism against anaemia. In studying the significance of protein in vitamin-E deficiency, Loosli and his colleagues found that an adequate casein allowance ensured rapid growth in young rats even when abnormalities in the incisor teeth plainly indicated deficiency of vitamin E. The administration of tocopherol ensured normal teeth even in rats stunted by severe protein deficiency. Interaction between protein and vitamin E was shown by a slight improvement in growth when rats moderately deficient in protein were dosed with tocopherol, and also by a clear superiority in the teeth of rats deprived of vitamin E but given adequate protein as compared with those of animals deprived of both nutrients. Animals revived for long periods on a diet extremely low in protein when tocopherol was administered, but died with massive necrosis of the liver, as described by previous workers, when vitamin E was given. No liver abnormalities were found in vitamin-E deficiency when the protein intake was adequate; deficiency of protein with the administration of tocopherol used severe fatty infiltration in the liver in spite of the good general health of the animals. Hove reported that rats deficient in both protein and vitamin E developed zonal necrosis of the liver and fatal lung haemorrhages within two months, and that

these lesions occurred after only three to four weeks if the animals were dosed with carbon tetrachloride, benzene, or alloxan. The injuries were prevented by tocopherol or by an adequate protein allowance, but casein oxidized by treatment with hydrogen peroxide was ineffective, as also were cystine, methionine, and tryptophan.

Schwartz claimed that three fundamentally different types of fatal liver injury may be produced in rats (1) by giving a diet containing casein treated with alkali, (2) by feeding large amounts of cod-liver oil, or (3) by using dried yeast, which is deficient in sulphur-containing amino-acids, as the source of protein. When cod-liver oil was given in conjunction with yeast protein, death occurred from severe degeneration of the heart and acute oedema of the lungs before the liver changes had time to develop. Lesions caused by restriction to yeast protein could be prevented by cystine or methionine, while tocopherol prevented all the lesions mentioned. György and Rose found that the red blood corpuscles of rats kept on diets deficient in vitamin E, even for short periods, were rapidly haemolysed either on injecting the animals with alloxan or its reduction products or on treatment of the corpuscles *in vitro* with dialuric acid. While tocopherol prevented the tendency to haemolysis, it did not prevent the development of diabetes.

Farm Animals

Experiments on farm live stock have suggested that deficiency of vitamin E in the pregnant female does not cause resorption of the foetuses or abortion, although the vitamin is important in maintaining the health of both young and adult animals. In bovines kept on a deficient diet, consisting mainly of rice straw, Gullickson noticed no failure in spermatogenesis, nor in the size or vigour of calves which were carried to term. A high proportion of the heifers, however, died suddenly, usually during or shortly after pregnancy; one bull also succumbed. Electrocardiograms taken at frequent intervals suggested that the deaths were due to heart failure. Carpenter and Lundberg observed that the incidence of "baby pig disease," which is probably a virus disease of the influenza type, was significantly reduced by supplementing the sows' diet, which was of good quality, with additional allowances of tocopherol. Loosli found that the lambs of ewes kept on a diet of alfalfa hay and beans developed a muscular dystrophy which could be cured or prevented by tocopherol. Although the diet was not deficient in vitamin E, the levels of tocopherol in the blood plasma of untreated animals were abnormally low.

Loosli also confirmed the effect of tocopherol in improving the storage qualities of the body fat; in cows' milk the tendency to the development during storage of an objectionable flavour due to oxidative changes was checked. These observations may be correlated with the investigations of Dam, in which peroxidized fats have been detected in the adipose tissues of rats and chicks given diets deficient in vitamin E and containing large amounts of cod-liver oil.

Human Investigations

Quaife, Swanson, and Harris, in a study of the distribution of tocopherol in cases of accidental death, showed that most of the human body's stores of tocopherol, amounting to 3.5-8 g., were in the fat deposits. They estimate the daily intake of vitamin E in America at 10-25 mg., which is in substantial agreement with Engel's estimate of 15 mg. for the population of Holland. These data imply that vitamin E is quantitatively important as a constituent of the unsaponifiable fraction of human fat, approaching cholesterol in amount. Darby and his colleagues have found that the level of tocopherol in the blood plasma is influenced by disease, being lowered in conditions associated with an impaired absorption of fat and raised in metabolic disturbances characterized by hypercholesterolaemia. Normal values were found in women who had recently aborted, but Scrimshaw, Greer, and Goodland observed low levels in women who aborted between the seventeenth and twenty-fourth weeks of pregnancy as compared with those of pregnant women who did not abort during this period.

Claims that vitamin E is effective in the treatment of heart disease, of thrombophlebitis, arteriosclerosis and thromboangiitis obliterans, and of burns were put forward by E. V. and W. A. Shute. No controlled investigations were undertaken

by these workers, and critics suggested that the frequent occurrence of spontaneous remissions or cures could not be overlooked. The same criticism may perhaps be applied to several other investigations. Thus Ant and di Cyan formed the impression that in 100 cases of rheumatic diseases treatment with vitamin E mitigated pain, improved the mobility of the joints, and caused the regression of nodules and the reduction of swellings. Steinberg noticed improvement in 37 out of 40 cases of Dupuytren's contracture of the fingers after treatment with tocopherol, although he had no success in treating disseminated lupus erythematosus, diffuse scleroderma, or dermatomyositis. Scott and Scardino found that about 40% of their cases of Peyronie's disease, with painful erections and abnormal curvature of the penis, were improved. Pennock thought that vitamin E was possibly of value in treating six cases of thromboangiitis obliterans. Scardino and Hudson considered that some benefit was obtained in about half the cases of urethral stricture which they treated with vitamin E. Stritzler reported improvement in 14 cases of stasis dermatitis and in 11 out of 13 cases of stasis ulceration. Investigations by Dowd deserve attention on account of his impressive claims and his caution in using a control group of patients. After treatment with vitamin E all members of a group of 18 children with chorea, aged 6-17 years, were cured of choreiform motions, and their sleep and appetite were improved; out of 17 untreated subjects only two showed similar improvement.

The claims that tocopherol is valuable in the treatment of heart disease were contested by Travers and her colleagues, who found no differences in the serial electrocardiograms, exercise tolerance tests, or blood-pressure readings in groups of patients with heart disease treated or not treated with tocopherol. Donegan, too, had equally negative results in the treatment of cardiovascular diseases. Baer, Heine, and Gelfond examined patients with angina pectoris, hypertensive heart disease, and cardiac failure by physical examination and by electrocardiograms and ortho-diagrams over periods of three to six months. Treatment with α -tocopherol was invariably ineffective in causing improvement in the electrocardiograms or in decreasing the size of the heart. In the few patients in whom angina pectoris appeared to be improved equally favourable results were later obtained by the administration of a placebo.

Vogelsang claimed that when adult diabetic patients were given vitamin E their insulin requirements were decreased, and that after treatment for a year insulin was often no longer necessary. In contrast to a claim by Butturini, tocopherol did not decrease the blood sugar in normal subjects. In juvenile diabetic patients Guest observed no improvement after treatment with tocopherol.

POSTGRADUATE MEDICAL EDUCATION NEW JOINT BOARD

A Joint Board has been established by the Royal College of Physicians, the Royal College of Surgeons, the Royal College of Obstetricians and Gynaecologists, and the British Postgraduate Medical Federation. As announced briefly last week (917), the Board, under the chairmanship of Sir John Anderson, has been set up in order to effect co-operation between the three Colleges and the Federation in providing postgraduate education in the medical and dental specialties. The Joint Board is to consider existing provisions for the postgraduate education and training of specialists, and to invite the attention of medical schools and institutes, hospital authorities, and other bodies providing postgraduate medical education to such modifications as may from time to time appear desirable.

Since its establishment the Joint Board has paid particular attention to the procedure for giving postgraduate students advice on suitable hospital appointments and programmes of study. For this purpose the services of the staff of the central office of the Federation are available, and each Royal College has arranged to provide expert advice and guidance for suitable candidates for its higher qualifications and for other graduates visiting this country for the purpose of further study. In addition a small central advisory committee has been formed to assist the central office of the Federation to deal with other postgraduate students and to consider problems of common

interest. The Board is concerned especially to establish co-operation with medical schools, boards of governors of teaching hospitals, regional boards, and hospital management committees in order that potential specialists may obtain suitable hospital appointments. It is hoped that the new arrangements may prove of value not only to graduates of the United Kingdom but also to those from universities overseas.

LEPROSY IN THE BRITISH EMPIRE LONDON EXHIBITION

The "Belra" (British Empire Leprosy Relief Association) Exhibition at the Academy Hall, Oxford Street, London, was opened by the Prime Minister on May 13. The exhibition, which is designed to bring home to the public the incidence of leprosy throughout the world, and especially in the British Empire, is far more than a collection of pictures. An African hut, made of real Nigerian mud, with palm-mat roofing, shows the type of home normally shared by a family of nine or ten people. The incidence of leprosy in different parts of the world is shown by relief maps. The history of the disease is also traced from the earliest records of its incidence in the Nile delta. A large-scale replica of the famous Itu colony, started by Dr. McDonald and his wife in Southern Nigeria twenty years ago, is another interesting exhibit; it shows a doctor, a nurse, and two assistants, who were responsible for treating over 5,000 in-patients. Stress is laid on the increasing number of cases of leprosy in Great Britain. The medical secretary of the association, Dr. Gordon Ryrie, stated at a press conference that he knew of over 50 detected cases, and that there are almost certainly as many more unknown to his association. This increase is due to the return of Servicemen and prisoners-of-war from abroad, to the arrival of both British and Eurasians from India and Pakistan, and to the presence in this country of a much larger number of foreigners than before the war. Dr. Ryrie pleaded for a section of a modern hospital in London where these patients could receive treatment under a whole-time leprosy expert. All the facilities of modern laboratories would then be available for the study of the newer drugs, and postgraduate courses could be arranged for doctors and nurses.

THE MEDICAL ART SOCIETY EXHIBITION

[FROM OUR ART CRITIC]

Judging from the Medical Art Society exhibition, which is on view at Walker's Galleries, 118, New Bond Street, London, W.1. until June 2, doctors are apt to pack their paint-boxes in their holiday suitcases and appear to find landscapes a pleasant retreat from surgeries full of their fellow creatures. Some are technically expert, some less so; but evidently they have all enjoyed themselves.

Perhaps the biggest difficulty for an amateur painter is to decide just what he really wants to make of a picture. Pictures after all, can be so many things: a sketch to remind you of a pleasant holiday, an accurate representation carefully carried out or something quite new and of its own, the result of looking at familiar objects as if for the first time. The majority of the doctors showing their work in this exhibition set out to record a scene, but a few here and there seem to have attempted the far more absorbing and fruitful task of seeing. Mr. Frank Forty, for instance, in his two canvases "Pont de la Concorde" (35) and "Sheephaven, Co. Donegal" (29) has created scenes consistent within themselves. His "Thames at Richmond" (21) was a more difficult subject, and here he has not been so successful in bringing the various parts into harmony. Dr. Edith R. Magill's "On the River Test near Houghton Village" (1) is an extremely sensitive picture which has caught the subtle play of tones between water, trees, and sky. Dr. L. Woodhouse Price's "A Surrey Barn" (13) has also a harmonious composition. Dr. Norman Patterson enjoys the texture of paint, and in "Pyrus Floribundus" (43) has used it to good effect. His "Glass Ball and Oranges" (67) is an interesting but rather less successful effort. Among the water colours, Dr. E. Goodwin Rawlinson's "Near Watford" (99) has an almost Chinese

restraint, and Dr. Henry Wilson's "Rainy Evening, Islington" (100) has exactly the glistening shimmer of a wet London night that can often make magic of the dreariest streets.

There are other exhibitors who have tried to create something but seem to have had difficulty in deciding just what was important in their compositions. For instance, Dr. Francis Roles has two paintings of the Thames (36, 55) which look restless because there are no predominating lines or colours. This fault may have come from too much preoccupation with technique, so that simplicity has been lost. Another artist who appears to have become too preoccupied with technique is Dr. Lorna King, whose exhibits last year were more spontaneous than her present Kentish landscapes (4, 9).

Among some traditional and extremely competent paintings are Mr. T. Holmes Sellors's "Winter, 1949" (75), Dr. R. Foster Moore's "Laksfors, Norway" (93), Dr. Reginald Morshead's "In Holmwood Park" (106), Dr. Hugh S. Stannus's "The Coast Path, Jersey" (109), Dr. C. Branwell's "Harvesting in Cornwall" (32), Dr. R. A. Beaver's "Porte de Halles, Brussels" (50). Sir Henry Bashford as usual has produced three very individual compositions which are not so intricate as at first sight they appear. His "Autumn Evening, Wiltshire" (122), for example, is almost as simple a composition as Dr. J. D. W. Pearce's delightfully naive "Early Morning in Tessin" (17).

On the whole the doctors seem to have cast their vote for Munnings against the moderns; the few who have not done so do little credit to modern art. Dr. W. J. Benzimra in "Still Nature" (53) has produced an attractive painting with colours derived from Gauguin, but those who show signs of being influenced by anyone of a later period than the impressionists seem to have reached the facile conclusion that anything dragged up from their subconscious minds is worthy to be put on record!

As the titles of the pictures show, landscapes predominate in this exhibition. It is remarkable that hardly anyone has thought of painting familiar objects in homes and surgeries. Dr. Cecil M. Ruben in "Daily Event" (16) has attempted a difficult domestic scene not unsuccessfully; but there must be many unexplored possibilities in medicine bottles, "old crocks" in waiting-rooms, laboratory benches, or—an obvious subject which has been almost entirely neglected—the human form.

ROYAL MEDICAL FOUNDATION OF EPSOM COLLEGE

PENSIONS, SCHOLARSHIPS, GRANTS

The Council of Epsom College invites applications for a "Hadlow" pension of £70 per annum for a medical practitioner or the widow of a medical man fully 60 years of age, and one or two St. Anne's Scholarships for girls attending Church of England schools. Candidates must be fully 9 years of age and the orphan daughters of medical men who have been in independent practice in England or Wales for not less than five years. The value of each scholarship is dependent upon the means of the applicant and the locality and fees of the school selected.

There are also available: (a) pensions for necessitous medical men fully 55 years of age, provided they have been registered for five years, for the widows of medical practitioners fully 60 years of age, and for the spinster daughters of medical practitioners of 55 years and upwards. Awards are made as vacancies occur. (b) Scholarships and grants for children of either sex, not necessarily orphans. Candidates must be of public-school age and in need of such help. (c) Grants from the Eastes Trust for the relief of registered members of the profession of any age, their widows and orphans, and for the educational assistance of their daughters or sons.

Full information and forms of application are available, on request, from the secretary, Epsom College, Surrey.

The Ministry of Health has appealed to hospital boards and management committees to start National Savings groups and to increase the activities of those in existence. Information can be obtained from the local Assistant Commissioner for National Savings, whose district office address can be obtained from the telephone directory under "National Savings Movement."

Preparations and Appliances

"PERSPEX" OXYGEN TENTS

Dr. G. M. KOMROWER, visiting paediatrician, Royal Manchester Children's Hospital, writes: Considerable effort has been made in recent years to improve oxygen therapy, but not many efficient and cheap appliances that can be used for neonates and infants have been produced. With the assistance of Peak Plastics, of Manchester, I have evolved two types of perspex oxygen tents. The first (Fig. 1), which is a total cover,

FIG. 1—"Total cover" type of oxygen tent.

measures 26 by 14½ by 11½ in. (66 by 36.8 by 28.5 cm.) and has been found most useful for premature and newborn infants. The second type (Fig. 2) covers the head and shoulders and has a skirt attached around the opening (E) to minimize oxygen loss. This type is made in two sizes, the larger measuring

FIG. 2.—Bell-tent type.

24 in. (61 cm.) in diameter by 12½ in. (31.5 cm.) in height, and the smaller 18½ in. (47 cm.) in diameter by 11 in. (27.5 cm.) in height. The tents are blown; this eliminates any riveting, and consequently they are inexpensive, unbreakable, and easy to wash and keep clean.

We find that an oxygen concentration of 40% can be achieved by running at 4 litres a minute for 30 minutes and then reducing to 2 litres (oxygen inlet D).

As perspex is a poor conductor of heat, the cot should first be heated by an electric pad or hot bottles and the temperature then maintained by the latter if necessary. In this way it should be possible to avoid the simultaneous use of oxygen and an electrical appliance, and thus the danger of explosion should be averted. The oxygen can be used direct from a cylinder or passed through coils which are surrounded by ice, and if a high humidity is required it could be bubbled through a water-bottle. Excess humidity can be dealt with in one of two ways: (1) opening outlet A and blowing oxygen through quickly for 10 minutes, or (2) the use of soda lime in container B. This will deal also with any possible increase in concentration of carbon dioxide.

The great advantages of the tents are: (1) the excellent view one obtains of the infant; (2) they are easy to handle, and can be disinfected with "dettol" solution, weak potassium permanganate, or mercuric iodide solutions; (3) they are very durable and cannot be damaged easily; and (4) they are very light and can be removed without any effort by the handles (C). It is suggested that the "total cover" tents be mainly reserved for premature and neonate infants, the smaller bell-tent for infants up to 10 lb. (22 kg.), and the larger for infants up to 16-17 lb. (35-37 kg.).

Nova et Vetera

THE MEDICINE OF MACROBIUS

The number of authors who attain immortality at second hand because their names have been mentioned by better writers is large. One of these unread immortals is Ambrosius Theodosius Macrobius. It is certainly a good mouth-filling name, but that would not have saved him. Macrobius, *tout court*, is read every year by thousands because it occurs twice in Boswell's *Life of Johnson* (see Powell's revision of Hill's edition, Oxford, 1934, vol. 1, p. 59; vol. 3, p. 25). Johnson surprised his teachers when he came up to Oxford as a lad by quoting Macrobius, and Boswell many years later quoted Macrobius to the doctor. We are not told what passage Johnson quoted to the Oxford dons, but may be sure it was not the one Boswell quoted, which the chaste editors of Boswell left in the obscurity of a learned language. Macrobius was edited by a learned German in the middle of last century (*Macrobii Ambrosii Theodosii, Opera quae supersunt*, ed. Ludovicus Janus. 2 vols. Quedlingburg d Leipzig, 1852), and embedded in much dullness one finds nothing of medical or at least physiological interest.

Historians of literature have not much to say of Macrobius. He was apparently a contemporary of the great Augustine of Hippo, and he may have been a very important person—a man of the same imposing name certainly was—but the case is made doubtful by the fact that to be a high imperial officer at that time it would have been necessary to be a professing Christian, and nothing in Macrobius's writings suggests that he was a Christian. It is probable that Macrobius, like Augustine, was a North African, and certain that, unlike Augustine, he was a good Greek scholar. The first volume of von Jan's edition may be left to philologists.

The second volume, containing the *Saturnalia*, is much better reading for an amateur. The plan is that a party of friends shall pass the Saturnalian public holidays as what the British Broadcasting Corporation would call a Brains Trust, discussing questions of general interest. Since Plato's day it was a favourite scheme, and, although schoolmasters would not think much of Macrobius's latinity, he carries out the plan with a good deal more vivacity than Cicero showed. He gets on good terms with

the reader quite early. When the friends are assembled a visitor is announced who is not pleased to find a party and says rather cattishly that he hopes he is not intruding on some secret meeting. Thereon one of the party remarks that certainly there are no secrets and, indeed, that he follows the rule *Sic loquendum est cum hominibus, tanquam dii audiant; sic loquendum cum diis, tanquam homines audiant*. This may be borrowed, but the learned editor does not say so; anyhow, it is a good phrase. The party then settles down to an account of the origin of the Saturnalia and other archaeological and philological matters, and next (after dinner, by the way) to the goodness or badness of jokes. Some of the jokes do not seem very funny, but the learned editor does now and then introduce a note of unconscious humour. One of the jokes is the story of Augustus, who, seeing a young man in Rome much like him said: "Was your mother ever in Rome?" and received the reply, "No, Caesar, but my father often was." The editor has a footnote pointing out that this was an aspersion on the legitimacy of the emperor. Eventually the brains trust settles down to medical or physiological questions; it is this part—from chapter 4 of the seventh book to the end—which has medical interest. The radio doctor is Disarius, a Greek who is treated with that mixture of respect and faint mockery which is in the Roman tradition.

The first question proposed is whether a simple or a complex diet is the more hygienic. The doctor leads off with a plea for simplicity; he remarks that cattle fed on simple diet are much healthier than human beings, but those fattened on mash (*offa compositae*) do suffer from diseases. Then no doctor would give a patient in a fever anything but a simple diet. Again everybody knows that mixing drinks is unsound.

These are matters of observation, but scientific reasoning leads to the same conclusion. There are four stages of digestion (we should say assimilation)—the coction in the stomach, the change into blood by the liver, changes in and transport by the blood vessels to the tissues, and, finally, assimilation by the tissues. But if the stomach has to deal with a great variety of foodstuffs, some needing more, some less coction, there is likely to be more trouble than when the diet is simple: the wrong ingredients may reach the tissues and the result may be humoral changes which produce gout and rheumatism.

This exposition (of course it is much longer than this abstract is well received, but another member of the brains trust Eustathius, is urged to try his hand as a critic. He scores bull's-eye with his first shot by reminding Disarius that so-hygienic sheep and cattle live shorter lives than men, a fact that according to Homer some pestilences which destroy men began in cattle. (The authority of Homer or Virgil was as formidable a weapon in such debates as a quotation from Marx or Lenin in modern communist circles.) Also, is a diet of herbivora so very simple? Are not the pastures different fields very different?

Warming to his work, Eustathius points out that man is a highly complex animal and surely needs a complex diet, the eating of the food one enjoys favours coction. Gluttony is always wrong, but a glutton can stuff himself with olives alone or cabbage alone. If variety is bad, what about medical prescriptions? Eustathius evidently has the majority with him, and Disarius tactfully congratulates him on his knowledge of medical dialectic and adds: "Whoever wishes to choose the right path let him learn from practice; what will be good for health, experience will decide (*Qui vult eligere sequenda ut consulas, et quid sit utilius sanitati experientia docebit*)."

The brains trust dealt with many dietetic problems, some of which are mysterious. Thus Disarius is invited to explain why minced meat is difficult to digest. He does not dispute the fact but attributes it to the propensity of finely divided food to pass into the semi-fluid contents of the stomach and so to escape contact with the wall of the stomach, the heat of which promotes digestion. The explanation is not satisfying, but one remembers minced chicken as a diet for invalids might dispute the fact the doctor attempted to explain. However, Disarius has been right; in these days of austerity in England meat dishes with pleasant names are—mince. But the meat through the mincing machine is hardly of the quality of meat minced for invalids in nursing-homes of long ago.

MAJOR GREENWOOD

Correspondence

Treatment of Basal-cell Carcinoma

SIR,—I must quarrel with Sir Cecil Wakeley and Mr. Peter Childs's treatment (April 30, p. 737) of basal-cell carcinoma. Their assertion that "there should be no recurrence with adequate surgical excision" is fair enough, and, indeed, providing sufficient emphasis is made on the word adequate, it is true in the case of malignant disease anywhere, no matter how advanced. Having gone so far, I am surprised they go on to say, "In almost all cases rodent ulcers may be treated in the out-patient department under local analgesia." This, of course, is not adequate treatment of a basal-cell lesion, and if this advice were faithfully followed the recurrence rate would shoot up from 5% (following radiotherapy) to something well over 50%.

The majority of rodent ulcers occur on the skin of the face—the inner canthus, eyelids, ear, and nose being particularly common sites. The "adequate" surgical excision of such lesions is very often mutilating, and most surgeons, quite naturally, tend to preserve as much normal tissue as possible for cosmetic reasons. Inevitably a few cells will be left behind in quite a fair percentage of cases, and the lesion recurs or, more accurately, residual cells continue to grow and divide.

Sir Cecil Wakeley and Mr. Childs state, "Only rarely need a patient be condemned to irradiation on account of poor health." In actual fact radiotherapy is a first-class treatment for practically all basal-cell carcinomata, and the only exceptions are those lesions which occur in sites which are particularly sensitive to irradiation, such as the foot, and also those lesions which recur after irradiation. The great majority of the lesions can be treated by a simple, single 15-minute exposure of x-irradiation. Seldom does depth of penetration of the lesion interfere with effective radiotherapy, and cure is not uncommon even in those quite inoperable lesions, now happily rare, of very many years' duration which have extensively destroyed normal tissues. The cosmetic results following radiotherapy are excellent on the whole, and in many cases it is not easy to detect the treated skin. Gross skin damage due to irradiation is uncommon except in the case of those extensive recurrences, previously irradiated and beyond surgery, which inevitably have to be re-irradiated.

Finally, I think it is true to say that from the treatment point of view there has in the past twenty years been a steady and impressive improvement in the malignant situation in several sites, and I think this is more due to improvements in radiotherapy techniques than anything else. It is a fact that only 5% of basal-cell carcinomata recur following good radiotherapy, and I maintain that this is a real achievement. To return to the days of excision under local analgesia in out-patient departments would be a step backwards.—I am, etc.,

HULL.

KENNETH W. BEETHAM.

Cow's Milk and Tuberculosis

SIR,—*Agriculture*, the journal of the Ministry of Agriculture, in its number for May, 1949, gives the following corroborative evidence of the danger of infection from cow's milk. Under the heading, "Farming Affairs—Whey-fed Pigs," it says:

"The incidence of tuberculosis in pigs fed on whey is high, and in such pigs the disease is often acute. Consequently, the carcasses of pigs fed on whey are more frequently condemned on account of tuberculous infection than those of other pigs. To guard against this danger, all whey should be boiled before it is fed to pigs."

—I am, etc.,

Winchester.

W. E. C. LUNN-ROCKCLIFFE.

An Unfortunate Precedent

SIR,—The profession, for good or for ill, has chosen the path of socialization and planning. Instead of a natural spontaneous growth, with extension here or recession there in conformity with the strains and stresses of supply and demand—cause and effect—there has been substituted a central control

to take over these functions. This central control has to try to foresee and to provide for every professional activity and contingency, small and large, imminent or remote.

Previously a professional man's reputation depended upon ability, industry, personality, opportunity, and luck. Now it will depend not inconsiderably upon the organized plans and dictates of authority. However omniscient, omnipotent, and benevolent the central authority may be, it remains the central authority; and so long as its decisions and opinions rule and organize medicine the profession will have lost its freedom.

These are the reasons basically for the present variously expressed reactions against the Committee for Distinction Awards. But the profession has, by and large, voted for this regime or regimen, and it must swallow the dose and like it. It has substituted political expediency for scientific principles, and will learn only by long and bitter experience that the change is scientifically and professionally for the worse.—I am, etc.,

London, W.1.

GEOFFREY BOURNE.

SIR,—The letter from the eight distinguished physicians who are Censors or other officials of the Royal College of Physicians would not deceive a politically immature rabbit, and should not bamboozle a single licentiate of the College. It is really a defence of presidential infallibility. Lord Moran's personal integrity has not been attacked, but the idea of the Awards Committee as such, and of his chairmanship, is open to examination in the light of history and of common sense. I will certainly defend the President's personal integrity, industry, or administrative ability, but I will not defend his views on the Health Service, his relation to the Government, or the relation of the College to the Government.

The centralized grading of the medical profession is nonsense. The language and methods of the cattle market or of Cruft's have no place in a liberal profession, whatever the integrity, intelligence, or ability of the graders, or their capacity to weigh evidence. How is it possible to equate the claims of the teacher, the research worker, the writer, the originator, the thinker, the administrator, the clinician, and the artist? Are we to breed for beef or for brain, for quietness in harness or for originality? It would take the wisdom of Solomon to arrive at anything more than the roughest and readiest of answers. The Censors' comment on this grading is that it is a "novel idea," though the phraseology suggests the lucky dip or the Christmas cracker. But at least the "novel idea" was sponsored by Lord Moran, and Lord Moran becomes the first chairman of the Awards Committee at a salary of three thousand guineas for the first year.

The history of the Royal College of Physicians is largely a history of medical monopoly and patronage. As long as these things are safe, the rest can go hang. Under the Health Act the monopoly instinct of the College is fused with the monopoly-loving instinct of a political philosophy. The infallibility of the President is, however, now subject to the still greater infallibility of the Minister. The College has proved a great convenience to the nationalizers of medicine, but it has taken good care to establish control over consultants through the State monopoly of the hospitals. Sir Henry Halford was, as you point out, the longest in office as President, with 25 years to his credit. George IV was certainly a man who knew his way about town, and this is how he wrote to Sir Henry:

"The King sends his kind regards to Sir Henry Halford and acquaints him that it is the King's intention to take an opportunity of appointing Dr. Southey, one of his physicians-in-ordinary, in the room of Sir William Knighton, who has desired, from the heavy pressure of his other situation, to retire from the responsibility of this."

"The King would have been glad if Dr. Southey had been a graduate of either of the English universities, and the King wishes that Sir Henry would supply this deficiency by making him a fellow of the College. The King mentions this as a continuation of the same feeling, which induced him on a former occasion to state to Sir Henry that the President of the College of Physicians should in future, for the time being, always be a physician-in-ordinary to the King."

"The King desires to express how sensibly he feels Sir Henry's constant attention, and the benefit which the King at all time derives from his great judgment and skill in his profession."

Dr. Southey received a Fellowship a few weeks later and shortly afterwards became physician-in-ordinary to George IV. The Royal Family soon got tired of having Presidents as hereditary physicians-in-ordinary, and the arrangement was cancelled.

The clue to the Censors' letter is contained in the statement that Lord Moran would be the first to admit how much he owed "to the sympathetic attitude of the Minister of Health." This statement suggests that the Minister is already a likely candidate for canonization by the College. Supposing the College had been asked to work out a design for patronage under the Health Act, how better could it have achieved this than by making the President the chairman of a Distinction Awards Committee? It is ridiculous to expect that the College will suddenly abandon its pretension to medical monopoly or to the exercise of its patronage. It is ridiculous to expect that Presidents will not be biased in favour of their own Fellows. It is ridiculous to expect that candidates for honours will not refrain from criticism of Presidents if it is likely to diminish their chances.

These criticisms are criticisms of the whole conception of the Awards Committee and the relations that now exist between the profession, the College, and the State. But they are not criticisms of Lord Moran's personal integrity. The College is now an organ of Government, and its proper place is inside the Ministry of Health, which is already the home of the Awards Committee. The College has abandoned all pretence of moral leadership, and again, behind the plea of unity, it asks for support for the Awards Committee in exchange for College support in getting more favourable terms for general practitioners. Perhaps we are not as green as the Censors think. At any moment I expect to get Captain Nye's "noon wire" recommending Plastic Lad, Sycophant, and College Boy for the Summer Meeting, with Sheer Merit as an outsider. But I shall keep my money till times are better.—I am, etc.,

London, W 1

REGINALD T. PAYNE.

Statistics and Health Education

SIR,—I must have expressed myself very badly, for Dr. W. Hartston (May 14, p. 866) has completely missed the point of my letter (April 16, p. 680). Of course all our schemes must be based on a knowledge of the facts—the wider the better—but what I am concerned with is the *usefulness* of the facts. Small boys collect numbers—of motor-cars or railway engines—and Government departments collect numbers—of everything they can think of. (In fairness to small boys it should be added that they only waste their own time and do not pretend that the results are of national importance.) The real question is, Are the most useful facts being collected?

Suppose the Ministry of National Insurance were concerned with the prevention of road accidents. According to their present method they would begin by collecting statistics as to the causes of death—fractured skull, crushed thorax, shock, etc.—and then proceed to devise means of preventing each individual injury. We might then see each bus passenger compelled to don a crash helmet and, indeed, a complete suit of armour when the steel situation permitted. Meanwhile there would have been no traffic lights, no warning signs, no cambered roads, and no attention to brakes. Fortunately, Sir, the prevention of road accidents has been tackled by intelligent, if somewhat ineffective, lay people, or the position would be much worse than it is.

Now, Sir, why should not the same method that is used to prevent road accidents be applied, but with much more vigour, to prevent illness? I am far from belittling the results which preventive medicine has achieved, though I do sometimes regret the complacency with which they are put forward. How much better off are we if people get influenza instead of malaria? Or if there is a marked decrease in scurvy and a marked increase in cancer of the lung? We aim at keeping people free from road accidents, whatever the pathological condition produced. Why not aim at keeping them free from disease, whatever form it takes?

Now this involves a knowledge of why people get ill at all, as opposed to what particular illness they get. Have we that knowledge at present? Every general practitioner could tell Dr. Hartston of cases where the strains and stresses which a patient has endured before he became ill have been a major

factor in producing that illness, but, as I said before, general practitioners are not given enough time to think. If a few of them were given time for research they could produce enough evidence to revolutionize our approach to preventive medicine. But would it? Dr. Hartston suggests that it would "get us no further than to convert this *crème de la crème* of G.P.s into clinical specialists or social statisticians"—in other words that whatever evidence they produced nobody would take any notice of it. Critical as I sometimes am of my colleagues in the public health field, I cannot but believe that on this occasion Dr. Hartston is doing them an injustice.

On another aspect of health education Dr. Hartston has completely—and perhaps wisely—evaded my question about the "lumbagos," but in his original suggestion he has raised an issue which cannot be evaded. If he starts "calling all lumbagos" from Luxembourg—or any similar propaganda to the sick—what about the G.M.C.? Now that body, which exists for the protection of the public, is displaying horse sense when it objects to treatment *in absentia*, for every patient is different from every other, and the doctor who has not seen the patient cannot treat him properly. Many of us must have wondered how some of our public health confrères have got away with it so far. One can only assume that the G.M.C. has hitherto regarded them as well meaning and relatively harmless people, but if they are to start radio propaganda in this way, can the blind eye be turned on them much longer?—I am, etc.,

East Hoathly, Sussex.

F. GRAY.

Malaria Prophylaxis with Proguanil

SIR,—The recent correspondence in the *Journal* regarding the occurrence of malaria in persons on prophylactic proguanil makes the case reported here one of some interest.

Both Dr. E. S. Walls (July 24, 1948, p. 225) and Dr. A. M. Best (Feb. 19, p. 324) report attacks of falciparum malaria in persons taking more than 0.1 g. of proguanil every other day, and both advise 0.1 g. daily as a prophylactic. The Colonial Medical Research Committee implements this advice in their recommendations (*Journal*, April 2, p. 585). The following case records a break-through of falciparum malaria in an expatriate taking 0.1 g. daily of proguanil as a prophylactic in an area in which falciparum malaria is endemic.

A European nursing sister had had several mild attacks of a fever of short duration. The fever was accompanied by headache, backache, and nausea, and characterized by a leucopenia, urobilinogenuria, and the presence of Türk cells in the thin films. No malaria parasites were found in thick blood films taken during the attacks, and in the absence of a definite parasitaemia the dengue group of fevers was considered as a probable cause of the pyrexia. Subsequent to the last pyrexial attack she had increased her dose of proguanil to 0.2 g. daily and had continued this for eight days, reverting to 0.1 g. daily thereafter. Thirty days after this attack she had an evening temperature of 101° F. (38.3° C.), and a thick blood film taken at this stage showed from 2–20 parasites in every microscopical field. All the parasites were young ring forms (trophozoites). The thin film showed some red cells containing two and three parasites per cell, parasites with double chromatin dots, and accolé forms. The film was typical of an acute falciparum infection commonly seen in children in this area. The white blood count was 3,800 per c.mm., and the urine gave a strongly positive test for urobilinogen. Treatment with increased proguanil and mepacrine aborted the attack, and the temperature became normal the following day, and has remained normal up to the time of writing. Gametocytes appeared in the blood on the fourteenth day after the commencement of the attack.

Since her arrival in the country nine months ago the sister had been taking 0.1 g. of proguanil regularly daily. She admits to having missed an occasional tablet, but states that at the maximum this did not amount to more than one a week, and usually was much less than this. It would appear in this case that a daily dose of 0.1 g. of proguanil was not sufficient to prevent the break-through of falciparum malaria.

We are indebted to the D.M.S., Nigeria, for permission to publish this account.

—We are, etc.,

FRANK DAVEY.
MICHAEL SMITH.

Uzuakoli, S.E. Nigeria.

Princess Tsahai Memorial Hospital

SIR.—May I beg the hospitality of your valuable columns to announce a reception at the Cora Hotel, Upper Woburn Place, W.C.1, on June 16, from 3 to 5 p.m., to welcome Lord Winstler, the chairman of the Memorial Hospital council, on his return from Cyprus, and General Cottam, who has just concluded seven years' magnificent service as head of the British military mission to Ethiopia? His Excellency, Ato Abeba Retta, the Ethiopian Minister in London, has kindly consented to be present. Brigadier G. S. Parkinson will preside, and Dame Irene Vanbrugh, Lord Amulree, and Mr. Hermon Ould will speak.

I should be pleased to send invitations to the reception on application by your readers, so far as accommodation permits. More than half the equipment for the Memorial Hospital (built in Addis Ababa by British subscriptions as a tribute of friendship to a gallant ally) has now been shipped from this country, and other goods will shortly sail. But the full target has not yet been reached; further purchases to make possible the opening of the hospital must still be made. Donations should be drawn in favour of the Princess Tsahai Memorial Hospital Fund and addressed to the honorary treasurers, Lord Horder and Lord Amulree, c/o Messrs. Gould & Pridaux, 88, Bishopsgate, London, E.C.2.—I am, etc.,

E. SYLVIA PANKHURST,
Honorary Secretary,
Princess Tsahai Memorial Hospital.

3, Charteris Road,
Woodford, Essex.

Curare-modified E.C.T.

SIR.—Drs. P. D. W. Shepherd and D. C. Watt (April 30, p. 752) give an excellent account of their technique for curare-modified E.C.T. I have had very little experience of E.C.T. in any form, but as an anaesthetist I feel that some comment is required on their method of induction and recovery.

The rapid intravenous injection, all in one syringe, of atropine, curare, and thiopentone is not to be recommended and sooner or later will lead to complications. They should be given in separate syringes: this gives a little more time for the atropine to develop its maximum effect (drying of secretions, etc.), and also enables a small test dose of curare (3–5 mg.) to be given without its effect, if any, being blurred by the accompanying thiopentone. After a pause of 1–2 minutes the remainder of the curare is given and immediately followed by the thiopentone—as recommended by Gray (*Ann. roy. Coll. Surg. Engl.*, 1947, 1, 191).

The use of an artificial airway should rarely be necessary. In most cases, and with a little practice, the airway of a curarized patient can be adequately maintained by holding the jaw forward, combined with gentle insufflation of oxygen: the slightly increased pressure of oxygen does, of itself, tend to push past a drooping tongue. The insertion of an artificial airway into a curarized patient who has had very little anaesthetic drug (e.g., 0.2 g. of thiopentone) can lead to regurgitation of stomach contents, or partial laryngeal spasm—rare occurrences, but not to be forgotten.

Finally, I should like to suggest more frequent resort to neostigmine: 2.5 mg. and 1/100 gr. (0.65 mg.) of atropine given as soon as the fit is completed neutralize the major portion of the curare in two minutes. To the best of our knowledge neostigmine has no toxic effects given in this way, and the early restoration of the patient's reflexes reduces the amount of supervision required per patient.—I am, etc.,

Liverpool

E. H. WINTERBOTTOM.

SIR.—We have read with great interest the article on curare-modified electric convulsion therapy by Drs. Peter D. W. Shepherd and David C. Watt (April 30, p. 752). After considerable experience of the method we are convinced of its value, but would like to join issue with Drs. Shepherd and Watt on several points in their article.

Like them, we originally based our technique on that described by Hobson and Prescott, but, unlike them, we have found it advantageous to use doses of curare somewhat smaller rather than larger than those advocated by them. The object of the curare is to soften rather than to abolish the convulsion, and only in very rare cases is any advantage gained by the complete abolition of muscular activity. It seems to us that the larger dosage renders the treatment unnecessarily time-

consuming and hazardous, and in unskilled hands may bring a valuable method into disrepute.

We have found the majority of cases could be adequately controlled by doses of 12 to 20 mg. of *d*-tubocurarine, and only in the case of very muscular individuals, active tuberculosis, or recent fracture did we consider it necessary to use larger doses. It has not been our experience that patients treated with these small doses are prone to develop troublesome laryngeal spasm.

With such doses of curare spontaneous respiration returns rapidly, and the patients can be left in charge of a trained nurse after a very short period of time. In this connexion we would also suggest that neostigmine or some similar preparation should be administered if there is any delay in the return of spontaneous respiration. The authors appear to have had it available but not to have used it.

It has been our practice to give doses of atropine intramuscularly from three-quarters to one hour before treatment is given. We have formed the opinion that the drying effect of the atropine is much more pronounced if it is given in this way than when combined with the curare and thiopentone injections.

In conclusion we should like to join with Drs. Shepherd and Watt in emphasizing the absolute necessity of having some suitable oxygen resuscitation apparatus available before the treatment is undertaken. This apparatus may be of the very simplest type, consisting of a face-piece and reservoir bag connected to the oxygen cylinder by a simple length of pressure tubing.—We are, etc.,

Dublin

Living Anatomy

SIR.—I apologize to my professorial colleague at Aberdeen for my temporary amaurosis (v. letter in the *Journal* of April 30, p. 778). I can only plead the recent acquirement of my first pair of bifocal spectacles—which I paid for. Would that I had waited six months for the free N.H.S. pair. *Mea culpa*.—I am, etc.,

Cambridge.

H. A. HARRIS.

Spermatolysis

SIR.—The article by Dr. Cafer Yildiran on spermatolysis (April 2, p. 575) raises several questions before one can accept the author's statement that this phenomenon alone was the cause of the sterility. There is no indication in the article that the wife was investigated, or that a Sim's post-coital test had been undertaken.

If his theory is correct, then lysis should take place in the vagina. Has this been investigated? Otherwise (since in the clinical notes the semen is reported as normal at the beginning of the investigation) clearly there is a possibility that such normal spermatozoa can escape into the uterus away from the lysis and so escape disintegration.

It would be interesting to know what the invasion qualities of such sperm were when tested by the Harvey method against known normal cervical mucus. It is rather dangerous to suggest that this factor (admittedly a new and interesting factor) may be the cause of sterility in the absence of any evidence that the wife was at fault. In any case, even on the evidence presented, it seems difficult to accept this theory altogether, since, after all, it is the spermatozoa and not the surrounding seminal fluid which enters the uterus, and there is no evidence to suggest that the sperm could not do this immediately after being passed. Much more evidence would be required before spermatolysis could be accepted as the sole cause of sterility in these cases.—I am, etc.,

Manchester.

BERNARD SANDLER.

Idiosyncrasy to Amethocaine Hydrochloride

SIR.—The recent correspondence on anaesthesia for bronchoscopy left the impression that there was little danger from amethocaine hydrochloride, provided the dosage was reasonable. This was not in agreement with my experience in four cases showing toxic signs, as the dosage in these cases had been normal. And this week it was driven home to me forcibly that idiosyncrasy, not overdosage, is the danger.

A young woman sucked a 1-mg. "nupercaine" lozenge before laryngeal examination. As she was uncooperative, this

was supplemented by two puffs from a fine de Velbis spray containing 2% amethocaine hydrochloride. Five minutes later she had a convulsion, and two minutes later a further convulsion was checked by intravenous thiopentone. Her condition remained alarming for a further 20 minutes.

The total dosage of amethocaine or its equivalent in this case was less than 10 mg.—i.e., less than 0.5 ml. of a 2% solution. The standard "decicain" lozenge contains 70 mg. of amethocaine hydrochloride, the equivalent of 3.5 ml. of 2% solution.

I think it is worth reiterating that any time amethocaine is used, whatever the dosage, a syringe and thiopentone should be ready for immediate use.—I am, etc.,

Market Drayton, Salop.

A. CLARK PENMAN.

Pressure Cooking

SIR,—In reading Dr. A. Orley's letter (May 7, p. 822) on the subject of pressure cooking, there appears to be an error of judgment. The supposed evils (post-prandial leucocytosis) of pressure cooking are surely applicable to all cooking. Dr. Orley states that "food has to be heated above 83°–87° C., according to the kind of food." These temperatures are approximately those of simmering in normal cooking. The boiling and baking of foods, for which much higher temperatures (up to 260° C.) are used, must on his reasoning result in a perpetual state of post-prandial leucocytosis for the majority of the population. Few people consume raw food with all their meals.—I am, etc.,

G. H. DONALD.

H 11 in Malignant Disease

SIR,—The appearance in the *Intelligence Digest* of April 1 of an account of the H 11 treatment of cancer has brought to a head a doubt that has been chronically festering in my mind since the publication (*Journal*, Oct. 16, 1948, p. 701) of the report on this subject by the Medical Research Council—shortly followed by further data from the Hosa Laboratories which could not be answered on the basis of the Medical Research Council's conclusions.

What angers me is not any conflict between the views of the M.R.C. and any personal views of myself, for I have none; it is that the Council, in what should have been one of the most important investigations it has undertaken, should so signally have failed to perform that one function which is the *sine qua non* of such a report—namely, the resolution of doubt. It is both ludicrous and outrageous that a body, performing only the function for which it was created, should be guilty of such a defection that neither the inquiring practitioner nor the fervently hopeful relative can feel that his mind has been put at ease by a final and lasting opinion.

It requires but one proved cure of a proved case of cancer by H 11 to necessitate an exhaustive clinical and biochemical investigation of its properties, and I have met no one who shares with the investigator appointed by the M.R.C. her confidence in the felicity of conclusions drawn from a superficial examination of a small and random selection of cases.

The decision must be made one way or the other; it must be shown beyond further question which of the parties is right. The present situation is intolerable.—I am, etc.,

BAOR

THOMAS BARRIE,
Capt., R.A.M.C.

Pain in Childbirth

SIR,—I have been very interested in the numerous letters published in recent weeks about analgesia in labour. Like Dr. Mary Herford (April 9, p. 634), I am a woman doctor with two small children, and I too gave much thought to muscle control and relaxation during the process of labour.

My first confinement proved very painful after the first few hours, because there was scarcely any pause between painful contractions. I was more than grateful for the application of the Young-Simpson inhaler, which gave me complete relief. I was able to continue for a further five hours with no operative assistance other than double episiotomy, in spite of the fact that the baby weighed 9½ lb. (4.3 kg.) and was persistent occipito-posterior.

The second confinement was naturally much more easy. I was able to relax during the contractions up to a point, but

again found I needed some relief. Crushing chloroform capsules gave some relief, but usually too late—their full effect coming on after the contraction had ceased. The Young-Simpson inhaler then proved perfect. The minute the pain becomes severe enough to cause deep breathing, the anaesthetic of choice (chloroform in my case) comes over, but as breathing becomes normal the inhalation of anaesthetic ceases and pure air is drawn in. The degree of pain controls the amount of anaesthetic. The result is perfect analgesia with rapid return to normality afterwards. If for any reason anaesthesia is required, all that is needed is adjustment of the valve by the professional attendant. On both occasions the Young-Simpson inhaler afforded me complete relief with no subsequent ill effects on myself or the infant.

From observation of patients in the labour ward and from my own experience and that of my friends I believe labour can be very painful in a great proportion of women. Understanding of the mechanism of labour, muscle control, and relaxation reduce the pain considerably, but when analgesia is desired, as is so often the case, I can think of nothing more simple for the attendant and more effective for the mother than this inhaler. Like Dr. Caiger Smith (April 9, p. 637), I cannot think why it is not in more general use. I am sure every mother who has used it would agree with me.—I am, etc.,

Cardiff.

DOREEN H. ANNEAR.

Continuous Irrigation in Prostatectomy

SIR,—The account by Mr. A. Wilfrid Adams of "a third ureter" in prostatectomy (May 7, p. 809) leads me to describe the use of a double catheter for continuous bladder irrigation following any method of "closed prostatectomy." The reasons which led to the use of this method are those described by Mr. Adams; and, as a registrar, these post-operative troubles of bleeding and catheter blockage have concerned me rather closely. I am aware that the method is not a new one.

It consists of using a Foley catheter (for want of any other two-way drain), which is passed through the penis and then has the bag cut so that fluid can pass through the smaller tube into the bladder and out via the large passage. The end of the catheter is cut off obliquely towards the two small holes, and two lateral holes are also cut toward the end, so that one or other will not be blocked by lying on mucosa. The catheter can be re-used by "railroading" it through the penis attached to an ordinary catheter.

At the end of the operation the usual precautions are taken to see that the tube is draining well, citrate is left in the bladder, and as soon as the patient is returned to the ward the small tube is connected to an ordinary transfusion set, using sodium citrate, and a continuous drip begun. The outlet tube is connected to a bedside bottle with a "dripper" attached, so that the nurses can see at a glance that all is well.

The advantages of this method are that clotting does not take place in the bladder and there is no longer the ever-present anxiety of a blocked catheter; the bladder is closed; and the irrigation is really sterile—being a closed system requiring only the changing of the citrate bottle, as in any intravenous therapy. The nursing staff, too, appreciate the saving of work and worry.

There has been no difficulty in estimating the urinary output. Although the lumen of the large section of the Foley catheter is smaller than that of a similar single-bore catheter of equal outside diameter, it is more than compensated for by the fact that any blood present is kept liquid and is diluted by citrate and urine. The results have been, so far, most satisfactory.

I would like to thank Mr. D. A. Abernethy for his permission to use this method and write this letter.

—I am, etc.,

Oxford.

H. D. MOORE.

Natural Childbirth and Sympatheticotonia

SIR,—In the leading article entitled "Natural Childbirth" (April 16, p. 669) you refer to the contention made by Dr. Granly Dick Read (p. 651 of the same issue) that rigidity of the cervix is a consequence of sympatheticotonia, and you point out that "not everyone will agree that this argument is correct on anatomical and physiological grounds."

In this connexion the experiments reported last year by the Swiss obstetrician Sauter¹ are of considerable interest. He found that atropine administered to women in labour never

produced a relaxation of the cervix, but in 14 out of 16 cases increased the rigidity. Conversely, "prostin" caused relaxation in 12 out of 14 cases and no effect in the other two. Yohimbine likewise effected a relaxation. These findings undoubtedly strengthen Dr. Read's argument.

Sauter found, however, that atropine simultaneously raised the tone of the corpus uteri, while prostigmin and yohimbine lowered it, and he concludes that the entire uterus is innervated both by sympathetic and by parasympathetic fibres and that both segments respond similarly to changes in vegetative tone. He also objects, on anatomical and physiological grounds, to the comparison between the cervix of the uterus and the sphincters of the bladder and rectum.

In another paper² Sauter reports the effect of dihydroergotamine (a sympatholytic agent devoid of the uterotonic action of ergotamine) in 43 cases of cervical spasm. Relaxation of the cervix occurred in all cases, and the basal tone of the uterus was generally lowered, with a corresponding increase in amplitude. The response to oxytocic preparations remained unimpaired.

There thus seem to be good experimental grounds for Dr. Read's contention that cervical rigidity, and hence much of the pain of childbirth, are the result of high sympathetic tone. Perhaps the sympatholytic drugs will turn out to be valuable not only for relieving true cervical spasm but also, in selected cases, for promoting "natural childbirth."—I am, etc.,

Basle, Switzerland.

Medical Journals for German Doctors

SIR.—Grateful acknowledgment is made to those doctors whose names I have not had, but from whom journals, like copies of *Pactolus*, have descended on me.

Letters and other parcels are being individually acknowledged. All parcels leave this month of May for medical schools of Germany and Austria, in the libraries of which they will be generally available. But all the schools—Freiburg, Göttingen, Berlin, Leipzig, etc.—are in need. The vacuum, in fact, is such that, should any doctor be in doubt as to where he may direct his aid, he may rest assured that, addressed to any of these university schools, journals would have much ado to stray.

If, in sending gifts to Germany, doctors here will provide a clue to the donor they will confer upon brethren across the Rhine an added grace in enabling them to express their thanks.—I am, etc.,

London, S.W.1

J. P. S. DUNN.

POINTS FROM LETTERS

Vertigo and Influenza

Dr. H. S. GASKELL (Stowmarket, Suffolk) writes: I am surprised that Dr. Peter A. Walford (May 7, p. 821) should find anything unusual in vertigo as a symptom of influenza. Although I find it mentioned in few, if any, books, influenza is by far the most common cause of giddiness. In a paper published in 1935 (*Practitioner*, 134, 646) I mentioned that it was not recognizable in 1932-3 but was "a constant feature" in 1934-5. It has been a constant feature ever since. If a patient walks into the consulting-room holding on to the furniture and complaining of a pain in the back of his neck there is no need for the G.P. to spend much time on the diagnosis. A few years ago, when I had a mild attack, I was afraid that I should be had up by the police, as I could not walk straight from the patients' houses to my car.

Vaccine Lymph

Mr. JOHN C. BRAYBROOK-NORMAN writes from the Pioneer Health Centre, Peckham: We have overcome the difficulty of expelling lymph from capillary tubes with an apparatus consisting of a small rubber bung the larger diameter of which is about $\frac{1}{4}$ in. (1.25 cm.). Starting at the wider end, a hole is burned for three-quarters of the length of the bung. Having chosen a piece of glass tubing to fit an available test, one end is reduced to fit this hole. The glass tubing is cut off sufficiently long to allow for the test to be affixed (total length about 1 in.). A slit is pierced with a Hagedorn needle through the remaining solid end of the bung to meet the larger hole. In use, one end is snapped off the lymph capillary tube and the open end is pushed through the slit to meet the larger-bore hole. The slightest pressure on the test is sufficient to expel the lymph, which is under control for the whole while. The adaptor may be sterilized complete or the parts treated separately.

Obituary

D. LLEWELYN WILLIAMS, C.B.E., M.C.,
LL.D., F.R.C.S.Ed., D.P.H.

Dr. Llewelyn Williams died at Liverpool on May 12 in his eightieth year. From 1920 until his retirement in 1935 he was a member of the Welsh Board of Health and the senior medical officer of the Ministry of Health in Wales. He will be remembered as an administrator. The smooth running of the old National Health Insurance scheme in Wales was due in no small measure to his administrative skill, his tactful diplomacy, and his unflinching good humour. He knew nearly every general practitioner in Wales, and he travelled the length and breadth of the country, especially in the early years, and did much to smooth out the difficulties of the hard-pressed practitioner confronted with a mass of new regulations.

David Llewelyn Williams was born in 1870, the youngest son of a Welsh Presbyterian minister. He was at school at Llandudno, and after some years as a pharmacist he entered Surgeons' Hall, Edinburgh, in 1895. A brilliant student, he took every medal and prize in each class he attended, and qualified in 1900. He was a house-physician at the Edinburgh Royal Infirmary, and he took the F.R.C.S.Ed. in 1904 and the D.P.H. in 1905. After a period at Leith General and Fever Hospitals he was appointed medical officer of health for the borough of Wrexham in 1905, and in the following year married Miss M. Price, of Rhyl. It was a happy marriage, and over forty years of comradeship ended only last year, when Mrs. Williams died. In 1907 Llewelyn Williams was appointed medical officer of health for the County of Denbigh, and was thus the first county medical officer in Wales. He did a great deal of pioneer public-health work in Denbighshire, and when the National Insurance Commission for Wales was formed in 1912 he was invited to join it as deputy medical officer. In August, 1914, he raised the Hygiene Section of the 38th (Welsh) Division, serving in the R.A.M.C. with the rank of captain. For his gallantry at Mametz Wood he was awarded the M.C., and the President of the French Republic honoured him for his work for French civilians behind the lines by awarding him the Médaille des Epidémies and the Médaille de la Reconnaissance Française. Dr. Williams was a member of the University Court of the University of Wales for many years, and was vice-chairman of the Council of the Welsh National School of Medicine from its creation in 1930. The University conferred the honorary degree of LL.D. on him in 1947. He had also been associated with the Welsh National Memorial for the Prevention and Treatment of Tuberculosis from its inauguration in 1912, serving on the council and on many committees.

A deeply religious man, Llewelyn Williams did a great deal of work for the Church in the mission field. He was an elder of his church, and spoke up and down the land on temperance and purity to enthusiastic gatherings of young people. On his retirement in 1935 he was appointed a member of the commission sent out by the Presbyterian Church of Wales to investigate their mission fields in India. When the second world war came in 1939 Llewelyn Williams, although 70 years of age, worked unceasingly on medical boards, making the difficult journey to Wrexham on six days a week from his pleasant home at Old Colwyn. To the end his interest in the University and the medical school continued. He will be greatly missed in Wales. He leaves two sons and a daughter.

Professor R. M. F. Picken writes: Public health and medical education in Wales have lost a staunch supporter by the recent death of Dr. David Llewelyn Williams. For many years he held a unique position in Wales. He was its first county medical officer when he was appointed to that post in Denbighshire, and, early recognizing the importance of public education in health, he travelled widely in North Wales in order to address meetings on the subject in the Welsh language. It would be impossible to overestimate the value of his influence in this direction. It was enhanced by the fact that he was not only deeply religious and had access to the congregations of the chapels throughout Wales, but was also a man of great physical

and moral courage, as his record in the first world war showed. His addresses were supplemented by pamphlets on healthy living, written in the Welsh language. When he became medical member of the Welsh Board of Health at its inception, he was responsible for the medical work of National Health Insurance as well as the supervision, inspection, and scrutiny of the public health work of the local authorities. He was the most approachable of men, and his advice was readily available to medical officers of health on the many difficult problems facing them during a period of rapid expansion of the service. Dr. Llewelyn Williams took a keen interest in medical education in Wales and supported from the time of the Royal Commission's Report in 1918 the proposal that there should be a Welsh National School of Medicine within the University of Wales. When it was ultimately established he became one of the first members of its council and subsequently its vice-chairman, an office which he filled with distinction and retained till his death. It was a matter of great satisfaction to the school that his services to the University were recognized by the award of the honorary degree of doctor of laws.

OWEN W. RICHARDS, C.M.G., D.S.O., D.M., M.Ch.,
F.R.C.S.

Sir Gordon Gordon-Taylor writes: Your obituary notice (May 21, p. 915) of Owen W. Richards prompts the following additional note. We had in the former War Collection at the Royal College of Surgeons of England several of his early specimens of successful resections of bowel, one of which (W.O. Coll. R.C.S. 865) was described in the following words: "Portion of small intestine showing twenty wounds produced by a fragment of shell. The piece of bowel which is 6 feet in length was successfully excised by Owen Richards, March 18, 1915. This was the first successful case of bowel injury dealt with on the British Front. Patient walked back with his intestines outside his abdomen, because he 'wanted to die in his own lines.'" The War Collection was completely destroyed by aerial bombs in May, 1941, and this historic specimen perished, but an illustration fortunately survives. Richards and the other "casualty clearing surgeons" were well acquainted with ileus, but their work was done in days before continuous gastric suction had even been dreamed of, and in the early war surgery of 1915 Owen Richards thought he had found an answer to the problem in extensive intestinal resection, carried wide especially on the proximal side of the damaged bowel, this procedure being based on Barker's teaching in cases of strangulated hernia where intestinal ablation was necessary. Greater experience, however, led Richards subsequently to discard this opinion and practice. To me his name is specially associated with Barlin and 6 C.C.S. in the First Army area, where for more than two years he had associated with him another fine surgeon, Tudor Edwards, who always considered himself most fortunate in this particular surgical environment. What a scintillating constellation of brilliant surgeons revolved round Cuthbert Wallace in the old First Army! There was none to match it for wealth of surgical talent. One of Richards's aphorisms relating to abdominal cases swayed the decisions of forward surgeons when overwhelmed with multitudinous and urgent cases: "It will be wisest to set aside those with abdominal wounds that are too late, too bad, or too high up." Owen Richards and Cuthbert Wallace—wartime abdominal surgeons owe much to the vision and practice of the former and the inspiration and leadership of the latter. *Ne obliviscaris*.

Dr. DONALD SARGENSON TWIGG died suddenly on Jan. 23. Dr. Twigg received his medical education at the University of Sheffield and took the conjoint diploma in 1914. He served as house-surgeon and house-physician at the Royal Hospital, Sheffield, and on the outbreak of the first world war joined the 3rd W.R. field ambulance. He served in France until the end of the war and then was sent out to Russia. After his demobilization in 1919 he started in practice at Hartington, and from then to the time of his death gave devoted service to the patients in his extensive practice in Derbyshire and North Staffordshire. During the second world war he was M.O. to the 10th Derbyshire Battalion of the Home Guard. He was hard at work up to the day of his death, which came as a great shock to his friends and patients. He leaves a widow, to whom the sympathy of all his colleagues will be extended.—J. H. C.

Medico-Legal

CUMULATIVE ACCIDENTS

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

The Workmen's Compensation Acts allow compensation for personal injury by accident arising out of and in the course of the employment. From early in their history the courts, desiring to give injured workmen every possible benefit of the Acts, have tended to widen the concept of "accident" to include a number of mishaps which, resulting from cumulative processes, could not even by a great stretch of imagination have been called accidents by an ordinary person. These "accidents" have included infective diseases. In 1905 a workman who contracted anthrax was held to have suffered an injury by accident, the accident being constituted by the entry of the bacillus. Hernia and Raynaud's disease following the continual impact of pneumatic tools have both recently been called accidents. The latest development in construing infections as "accidents" was that in which the Court of Appeal, by two to one, granted compensation to a nurse who had contracted tuberculosis while nursing tuberculous patients.¹

Lords Justices Cohen and Denning agreed with the finding of the county court judge that every time the nurse inhaled bacilli an accident was constituted. Though it might not be possible to fix the exact dates when the accidents occurred, they all took place in the course of her employment, and the effect was due to one or more of them. Lord Justice Bucknill dissented, holding that the disease was the result of a gradual process of breathing air containing noxious bacilli, and that there was no evidence to put it into the category of accidents. Leave was given to the corporation to appeal to the House of Lords. One must not presume to anticipate their Lordships' decision, but it is not many months since they refused compensation to a workman who had contracted silicosis at work.²

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examination indicated:

DIPLOMA IN MEDICAL RADIODIAGNOSIS.—Part I: A. C. E. Cole, J. B. Fox. Part II: J. H. E. Bergin, W. R. Cole.

Nearly £2,250,000 worth of streptomycin was supplied to European countries under Marshall Aid in the first year of E.R.P. operations, according to a British United Press report. France alone received £1,500,000 worth and Italy some £500,000 worth. Smaller quantities went to Holland, Austria, and Greece. In addition, France is to receive more than £125,000 worth of U.S. equipment needed for the reconstruction of two French factories to produce penicillin. These factories, both near Paris, will produce enough to supply France's minimum needs and at the same time to earn valuable Marshall Aid dollars. Cultures for the penicillin-producing fungus must continue to be supplied by the U.S. States for these factories, however, until French penicillin cultures are established.

Medical Notes in Parliament

NURSES BILL

The Nurses Bill was considered by the House of Lords in committee on May 17.

Lord LLEWELIN moved an amendment to Clause 2 which would put the boards of governors of teaching hospitals into the same category as other authorities. His amendment provided that the standing nurse-training committee for the hospital area should advise and assist boards of governors of teaching hospitals if those boards made a request to the committee. He said it was no use for a committee to approach Guy's or Bart's Hospital and proffer advice to people who were not prepared to receive it. If it was thought that because they held the purse strings the standing nurse-training committees were to dictate to the great teaching hospitals the Bill would not succeed.

Lord SHEPHERD replied that the teaching hospitals were specially designated as future members of the committee and were therefore in a special category. These committees, when established, would probably consist very largely of persons engaged in hospital work. If the regional hospital boards and the boards of governors got together and discussed the interests of their region, there need be no fear of victimization of one side or the other. The Government wanted the relationship of teaching hospitals to the nurse-training committees to be exactly the same as that of the hospital boards. They were anxious to benefit from the experience, influence, and leadership of the teaching hospitals.

Lord Shepherd mentioned that in the North-Western Metropolitan Hospital Board area there were in training 3,179 student nurses and 676 mental nurses. If the hospital services in that area were to be kept going with an efficient nursing service there must be an intake every year of 1,200 on the general nursing side and 450 on the mental nursing side. He feared that if the amendment was accepted a number of hospitals which needed help and assistance might take the opportunity to remain outside.

Lord WEBB-JOHNSON said Lord Shepherd had not indicated the precise composition of a standing nurse-training committee. Rumour had it that the representation of the teaching hospitals would be meagre. He believed that the committee would be practically a committee of the regional board, and the regional board was to be responsible for providing its officers and servants.

Lord LLEWELIN said that under the Act of 1946 the teaching hospitals went direct to the Ministry and not through the regional boards. Now Parliament was to set up standing nurse-training committees to which teaching hospitals must go if they required any sort of grant. These hospitals feared they would have to go cap in hand to a committee on which they might have perhaps one representative. Lord Llewellyn thereupon withdrew his amendment.

On Clause 3 Lord SHEPHERD moved amendments, which were accepted. One of these was drafted, he explained, to ensure that nurses who went through training under an experimental scheme should be given opportunities of becoming really efficient and that the approved schemes should give that guarantee of efficiency.

Proposed Hospital Grants Committee

Lord LUKE then moved to omit Clause 4 and to substitute:

"The Minister may, by order, constitute in accordance with the Schedule of this Act (Constitution of Hospital Grants Committee) a Committee (in this Act referred to as a Hospital Grants Committee) for the purpose of approving expenditure by a Hospital Management Committee appointed by the Regional Hospital Board for the area or by the Board of Governors of a teaching hospital situated in the area, being expenditure:

(a) wholly or mainly for the purposes of, or in connexion with, the training of nurses; and

(b) of such description as the Minister may specify for the purposes of this subsection."

Lord LUKE said it seemed illogical to depart from the principle established by the National Health Service Act of placing teaching hospitals in a separate category and of giving them a certain independence. This Bill sought to give those hospitals money at second hand instead of direct from the Minister. Under the National Health Service Act had there not been co-operation between teaching hospitals and the rest? Why was Parliament now departing from the principle laid down in that Act? The amendment he proposed sought to set up a hospital grants

committee to administer the funds required by each institution for the training of nurses. This would leave the standing nurse training committee and the General Nursing Council entirely free to concentrate on nursing standards, but there would be full consultation between the hospital grants committee and the standing committees.

Lord SHEPHERD said there was a desire that the training of nurses, instead of being provided entirely by the hospitals should be carried out by a body representative of the nurse and of other bodies but acting independently. To give that independence the expenditure to cover the training of nurses would come from the Government through the General Nursing Council to the training committees. It would not be right to compare the payment of these moneys with the method adopted by the Government in the case of the universities. When the Government decided to place moneys at the disposal of the universities no national organization existed for that purpose and therefore a body had to be created to carry out the allocation. This was not the case with nurse-training, because the General Nursing Council could well undertake the business of superintending the allocation of Government aid.

There were 600 training schools in this country, and a series of standing nurse-training committees was to be established. These committees would be agents of the General Nursing Council. These training committees would not rule the roost and the teaching hospitals would not have to go cap in hand to them.

Lord WEBB-JOHNSON said that the University Grants Committee had been conspicuously successful, and its grants enormously benefited medical schools and the medical faculties. The medical profession would have been sorry to see placed in the hands of the General Medical Council the distribution of funds for the benefit of medical education.

Lord MORAN said the original decision to keep teaching hospitals outside the regions was made so that they might continue to give a lead in medical education. Every argument used on the Government side in favour of that course was applicable to the issue now before the House. His friends were concerned to see that the teaching hospitals, which in the past were mainly responsible for progress in the training of nurses did not lose their opportunities to advance the art of nursing. The analogy between medical education and training of nurses was extremely close.

Lord LLEWELIN suggested that Lord Luke's amendment should be accepted and that thereafter between the committee and the report stages they should discuss who would be the right people to form the new body.

Lord ADDISON said he had much to do with the creation of the University Grants Committee, and during that period he met a committee of deans of the London teaching hospitals who with one accord exhorted him not to go on with "the dreadful thing." To-day they had the same kind of apprehension. The thirty-six teaching hospitals were not the only hospitals that taught nursing. There were 600 institutions which did that. Why should the people who had been pioneers wish to be isolated from the rest? The only object of the amendment was to put the teaching hospitals in a separate class. But the Government desired the benefit of their guidance and experience in the whole scheme. The Government was willing to have further discussions on the subject, but it must not be understood that it would change its view that its own proposal was the right one.

On a division Clause 4 in its original form was retained by 48 to 19.

Amendments were made in Clause 5, and on Clause 8 the House agreed to an amendment dealing with persons who had not fulfilled all the standards of training.

Lord WEBB-JOHNSON moved to insert after Clause 9 a new clause as follows:

"(1) The Council may if they think fit make rules prescribing or approving courses of training and prescribing or approving and for conducting or regulating the conduct of examinations to be undergone and passed by registered nurses desirous of specializing in particular branches of nursing, and may insert in the entry in the register relating to any registered nurse who has undergone the course of training and passed the examination prescribed or approved as aforesaid with respect to any particular branch of nursing such special signification as the Council may determine.

"(2) The provisions of subsections (1) and (2) of section sixteen of the Act of 1943 shall extend and apply to any rules made under this section."

He said anxiety was felt lest nurses sent to fever hospitals or mental hospitals or those nursing children for short periods during their training should thereafter be regarded as experts.

Lord ADDISON said what the Government desired was a good standard qualification. If in the course of time these extras were found to be necessary they could be provided. It would

A NON-MERCURIAL FUNGICIDE FOR TINEA PEDIS

The summer season brings an increase in the number of cases of epidermophytoses of the feet (athlete's foot) and similar mycotic infections of the axillæ and perineal regions. MYCIL is a non-mercurial fungicide, evolved in the laboratories of The British Drug Houses Ltd., which is strongly inhibitive to the growth of the causative organisms of tinea pedis.

MYCIL is issued both as an ointment and as a powder. Clinical results confirm the effectiveness of the combined application.

MYCIL Dusting Powder is particularly useful as a preventive against re-infection when clinical cure has been obtained.

... Now available
a synthetic curarising agent—

trade mark **'FLAXEDIL'** brand

Tri-(β-diethylaminoethoxy)-benzene triethiodide

In producing complete muscular relaxation during surgical operations the action of 'Flaxedil' is qualitatively indistinguishable from that of d-tubocurarine chloride. Pharmacological evidence suggests that it may prove to possess some slight clinical advantages including a greater sparing action on respiration, more rapid recovery and fewer side-effects.

'Flaxedil' can be administered by any anaesthetist who has had previous experience with d-tubocurarine chloride and its use requires no additional equipment or adjuvant drugs. Solutions of 'Flaxedil' are compatible with solutions of thiopentone sodium.

The synthetic preparation is equally suitable for moderating the convulsions of shock therapy and for controlling muscle spasm due to various causes.

Our Medical Information Division will be pleased to supply a copy of the medical booklet 'Flaxedil' on request.

DEFINITION FOR DIAGNOSIS

For a wide variety of radiographic procedures, a suitable contrast medium can be found in the Glaxo range. Individual diagnostic requirements can thus govern the choice of preparation . . . an all important factor in achieving dense, well-defined shadows. And testimony to the success of Glaxo radiological products is their growing use all over the world.

Introducing

'SYNCURINE'

A NEW MUSCLE RELAXANT

'Syncurine' brand Injection of Decamethonium Iodide (bistrimethyl-ammonium decane diiodide) presents a new synthetic compound (also known as C. 10) with a curare-like action. A single intravenous injection produces full muscular relaxation lasting from 15 to 25 minutes; repeated doses may be given as required.

Preliminary clinical investigations suggest that 'Syncurine' is a safe and highly satisfactory muscle-relaxing agent both for major surgery and for the control of electrically-induced convulsions in psychiatry. It is free from histamine-like activity and has no significant effect on the cardiovascular system. 'Syncurine' is issued in boxes of 6 and 25 ampoules, each containing 5 mgm. in 2.5 c.c. Further information available on request.

ANTIDOTE. An effective antidote, 'Wellcome' brand Injection of C. 5, containing 40 mgm. of Pentamethonium Bromide in 2 c.c., is available in boxes of 6 and 25 ampoules.

BURROUGHS WELLCOME & CO., LONDON
(The Wellcome Foundation Ltd.)

not be wise at present to incorporate in the Bill the words proposed by Lord Webb-Johnson.

Lord LLEWELIN said that in some cases additional certificates were thought to be essential. Would it not be possible for a special certificate to be given for the nursing of infants?

Lord AMULREE said the Hospital for Sick Children in Great Ormond Street and the similar ones in Manchester and Liverpool were at present recognized as full training schools for children's nurses. They should receive an assurance that there was no proposal to change that status.

Lord ADDISON said he had a strong prejudice against the multiplication of trimmings. They should view with misgiving people who collected large numbers of letters after their names. He was willing to discuss the problem again before the report stage. He said he could give Lord Amulree the assurance for which he asked.

Lord WEBB-JOHNSON then withdrew his amendment.

Clause 10 was approved with drafting amendments.

Lord SHEPHERD moved an amendment on Clause 11 to empower the General Nursing Council to charge a fee to organizations which asked for inspection and consideration, even though they were not finally given recognition by the Council. The amendment was agreed to.

Lord WEBB-JOHNSON moved an amendment to ensure that the complete cost of operations by the General Nursing Council under this clause should be borne by the Minister. Lord SHEPHERD said the Government could not accept the amendment, and it was withdrawn. Clause 12 and Clause 13 were approved.

On Clause 14 Lord LLEWELIN moved an amendment to ensure that the register of nurses should be published once every five years and the Council should not be relieved of their duty to keep an up-to-date list of alterations to the registry. He said that unless there was a register it would be very difficult to run an election for the General Nursing Council. Lord SHEPHERD said that if this amendment and the following one in the name of Lord Wolverton were withdrawn the Government would immediately appoint a working party representing the organizations involved, and he hoped this working party would report in time to permit an amendment being made to the Bill when it reached the House of Commons.

Lord WOLVERTON said his amendment proposed that amending lists should be printed as well as the present register. Lord SHEPHERD said a copy of the existing register could be obtained so long as copies remained. Lists of new registrations and lists of names removed from the register would be published three times a year, after the four-monthly examinations had been held. The amendment was withdrawn and Clauses 14, 15, and 16 were agreed to.

On Clause 17 Lord SHEPHERD explained that the Minister would be prepared to meet expenses incurred by the General Nursing Council in training nurses. Purely professional expenses should be borne by the General Nursing Council out of its own funds. If the Government gave way on this matter it would open the way for demands on the Exchequer from other sources. The clause was agreed to, as was Clause 18, with minor amendments.

A new clause was inserted in the Bill on the motion of Lord SHEPHERD to provide that the Council should annually make a report of their functions in connexion with training nurses during the preceding year, and that the Minister should lay this report before Parliament.

On the second schedule of the Bill Lord LLEWELIN moved that the majority of each committee should be registered nurses. He said that the British Medical Association, so far as he knew, was entirely composed of qualified doctors. Lord SHEPHERD said the Government accepted the amendment in principle, and suggested a discussion about its wording before the report stage. The amendment was withdrawn and the second schedule was approved.

Lord LUKE moved to insert a new schedule as follows:

"Constitution of the Hospital Grants Committee

"A Hospital Grants Committee shall consist of such number of persons appointed by the Minister of each of the following classes, as may be specified in the order constituting the Committee, that is to say:

- (a) Persons selected from lists submitted by the Royal College of Nurses,
- (b) Persons selected from lists submitted by the Central Midwives Board,
- (c) Persons appointed after consultation with the Minister of Education, and
- (d) Persons appointed after consultation with such Universities as the Minister thinks fit.

and the said order may contain provisions with respect to the qualifications of members of the Committee."

The amendment was accepted, though Lord SHEPHERD remarked that the Government agreed to it but did not approve of it.

On the third schedule Lord SHEPHERD moved an amendment to ensure that a mental-hospital matron appointed to the Mental Nurses Committee should be the matron of an approved training institution. The amendment was accepted. A second amendment to secure that the chief male nurse appointed to the same committee was a chief male nurse in a mental hospital which was an approved training institution was also accepted. The third schedule and the remaining schedule were approved and the committee stage ended.

Revised Estimates

Answering Mr. SHARP on May 11 Mr. BEVAN stated that regional hospital boards were revising their estimates, subject to a general directive that the welfare of the patients must not be affected. Detailed reports on the effect of the revisions proposed by the Ministry of Health had not yet been made by all boards. In the light of information so far received the Ministry was considering how far the proposed revisions should be carried out. Data were not yet sufficient for comparison of one regional hospital board with another. At least one year's full working was needed before such comparisons could be made.

Parkinson's Disease

Asked by Dr. SEGAL on May 12 whether the claims of Dr. Klemme in America to have cured cases of Parkinson's disease by operative treatment had been substantiated, Mr. BEVAN said the methods were well known but present experience did not justify their general adoption.

Dr. SEGAL asked whether, in view of exaggerated hopes raised by statements in certain sections of the Press, Mr. Bevan would appoint a commission of inquiry into this method of treatment. Mr. BEVAN replied that if he appointed a commission of inquiry each time a newspaper made exaggerated claims for some particular form of therapy he would have a number of commissions running all the time.

Mr. FRANCIS NOEL-BAKER asked whether Mr. Bevan knew that Dr. Voeller, in Germany, had had similar claims made about him. He asked Mr. Bevan to have the claims investigated, and if they were substantiated to make representations to the Treasury to give facilities for people to go to Germany to take this treatment.

Mr. BEVAN replied that that claim was of a different kind entirely. He had previously said that he was having it investigated.

Health Services in Northern Ireland

The number of persons registered with doctors under the Northern Ireland Health Scheme exceeded 1,200,000 and represented about 95% of the population, according to a statement made by the Minister of Health and Local Government in the Northern Ireland Parliament. During the first nine months of the Health Scheme about 230,000 people received dental attention, which was equivalent to more than 20% of the people in a full year. In the same period pharmacists dealt with 2,800,000 prescription forms containing nearly 4,000,000 prescriptions.

If the Hospital Authority's hopes were realized, plans for the construction of new hospitals and the extension of existing establishments would result in the provision of about 300 additional beds this year and about 1,250 during the next five years. At the moment there were 7,840 general beds available, as against 7,590 when the Authority took over control of hospitals. The total number of beds available for cases of tuberculosis was 1,380, or 275 more than when the Authority assumed control. The Authority estimated that about 700 additional beds were required, and it was anticipated that existing plans would provide some 250 to 300 of these within the next year.

Remuneration of General Practitioners

On May 19 Major TUFTON BEAMISH asked whether Mr. Bevan knew that the East Sussex Local Medical Committee, representing about 360 general practitioners in the National Health Service in East Sussex as well as others not in the Service, agreed with the General Medical Services Committee regarding their views following his recent meeting with them to discuss the case for increased remuneration of general practitioners, and what action he proposed to resolve the deadlock.

Mr. BEVAN answered that there was no question of deadlock. He was in the midst of negotiations with the General Medical Services Committee on the remuneration of general practitioners. He preferred to defer his statement till the conclusion of these negotiations.

No. 18

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 7.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

|| Includes puerperal fever for England and Wales, Eire, and Northern Ireland.

EPIDEMIOLOGICAL NOTES

Smallpox

Four cases of smallpox have now been notified in Liskeard: the original case admitted on May 7 and the three close family contacts who had been isolated in hospital as a precautionary measure. None of the other contacts showed any sign of the disease on the sixteenth day of surveillance.

A case of suspected smallpox has been reported on board the s.s. *Mooltan*, at present outward, bound to Australia. The liner left this country on April 28, and this patient was taken ill on May 18.

Discussion of Table

In *England and Wales* there was an increase in the notifications of whooping-cough 148, scarlet fever 113, acute pneumonia 41, typhoid fever 31, and dysentery 21. There was a decrease of 2,219 in the notifications of measles.

The largest declines in the incidence of measles were London 371, Essex 225, Middlesex 185, Lancashire 162, Yorkshire West Riding 139, Cheshire 127, and Sussex 102.

The rise in the notifications of whooping-cough was most marked in the southern section of the country; in the south-western counties 70 more cases were notified than in the preceding week. A small rise in the incidence of scarlet fever was reported from most areas.

Notifications of diphtheria fell to the record low level of 87, which was 5 below the previous lowest total recorded in January of this year.

An outbreak of dysentery affecting 14 persons was notified in Warwickshire, Warwick R.D. The only other large centre of dysentery was London, where 10 cases were notified from eight boroughs. The rise in the notifications of typhoid fever was due to the outbreak in Berkshire (Easthampstead R.D. 15 and Wokingham R.D. 16).

In *Scotland* decreases were recorded in the incidence of measles 53, whooping-cough 20, and scarlet fever 19. There was an increase of 11 in the notifications of diphtheria. The increase in the incidence of diphtheria was contributed by Lanark county and the city of Glasgow. Notifications of dysentery were practically confined to three cities: Glasgow 14, Edinburgh 11, and Dumfries 11.

In *Eire* there were decreases in the incidence of measles 28 and whooping-cough 30. Notifications of diarrhoea and enteritis increased by 21, and the total was the largest in recent months.

In *Northern Ireland* only small variations were reported in the trends of infectious diseases.

Week Ending May 14

Notifications of infectious diseases in England and Wales during the week included: scarlet fever 993, whooping-cough 2,906, diphtheria 90, measles 8,363, acute pneumonia 406, cerebrospinal fever 44, acute poliomyelitis 11, dysentery 77, paratyphoid 10, and typhoid 7.

Medical News

Royal Society of Edinburgh

The following members of the medical profession were elected Fellows of the Royal Society of Edinburgh on March 7: Dr. D. P. Cuthbertson, Dr. A. MacA. Gillespie, O.B.E., Dr. Harold Singleton, and Dr. R. H. A. Swain.

New Journal of Medical Records

The Association of Medical Records Officers has started a new quarterly journal called the *Medical Record*, which is issued free to members. It is edited by Mr. D. G. Davies, F.S.S., Records Officer of the United Leeds Hospitals. The journal will give news of the association's activities and provide an opportunity for the exchange of views for those working in medical records departments in hospitals and other medical establishments. Dr. Percy Stocks, Chief Medical Statistician of the General Register Office, contributes an article on "Records and Research," and emphasizes the importance of accurate initial records if statistical treatment of them is to be of use. The journal appropriately includes a crossword puzzle.

To Visit East Africa

Professor R. C. Browne, of the Nuffield Department of Industrial Health, University of Durham, will visit East Africa during June and July under the joint auspices of the Nuffield Foundation and the Colonial Office. He will represent social medicine among a panel of specialists visiting doctors in the Colonial Medical Service.

West London Medico-Chirurgical Society

The annual dinner of the West London Medico Chirurgical Society was held at the Royal College of Surgeons, Lincoln's Inn Fields, on May 18. Dr W. S. C. Copeman, the President, and Mrs Copeman received the guests, who included Lord Moran, Lord Burleigh, Sir William Gilliatt, Sir Cecil Wakeley, Sir Norman Birkett, Mr Somerville Hastings, M.P., the presidents of various kindred societies, and the editors of the *Lancet* and the *British Medical Journal*. The health of the society was proposed by Lord Burleigh, who took occasion to acknowledge the help given by members of the medical profession in connexion with the recent Olympic Games. He referred in particular to the work of Mr Arthur Porritt, a member of the society, who was chairman of the medical committee. Dr Copeman, in response, spoke of the liaison between the society and the British Postgraduate Medical School, as a result of which the society had had a considerable accession of new members, and the dean of the school was present at the dinner that evening not as a guest but in his own right. Lord Moran then presented the triennial gold medal of the society to Professor McCance for his work in the field of nutritional studies. He reminded the company that in the early part of the war Professor McCance had conducted experiments upon himself, living on a starvation diet in order to discover what was the minimum diet compatible with health. In a world menaced by food shortage the work of Professor McCance was of extraordinary value. Professor McCance, in acknowledgment, briefly discussed the special problems of experimentalists in medicine. He laid it down that any experiments made on patients not only must be undertaken with the object of curing the patient but also must proceed in consultation with the patient, who must be regarded not only as a subject but as an ally. He spoke feelingly of the searchings of conscience which this field of medicine demanded—embarrassments from which the ordinary practising physician or surgeon was free. Dr Doynne Bell proposed the health of the guests. Mr Justice Birkett, in response, told some excellent after-dinner stories, and also referred to his appearance this year as the society's Cavendish Lecturer. Mr Somerville Hastings also responded as a member of the governing body of the group of hospitals of which the West London Hospital was one. He said that so far as he had any influence the traditions of the West London Hospital would be maintained in the new regime.

More Rehabilitation

The Minister of Health is encouraging hospitals in the Service to increase facilities for rehabilitation. He has sent a memorandum to hospital boards and management committees saying, "The Hospital Service is responsible for the medical aspect of the problem in respect of the prevention or limitation of disablement by efficient medical rehabilitation concurrently with medical or surgical treatment. It is for the Health Service to prevent the large number of patients whose prolonged and ill-directed convalescence, after relatively minor disorders, causes so much absenteeism and often sows the seeds of a permanent disability neurosis." He emphasizes that practitioners should see patients through to the point where they can either resume their former employment or be passed to the Ministry of Labour's Displacement Resettlement Officers for placing in some suitable alternative occupation. The memorandum makes the following suggestions: (1) Appointment by each regional hospital board of a small committee to advise on development of facilities for medical rehabilitation; (2) nomination of responsible member of the medical staff at all larger hospitals to supervise the rehabilitation services; (3) extension of arrangements for long stay patients to undertake productive industrial work; (4) holding short courses for doctors to demonstrate modern methods of rehabilitation and resettlement.

Book on Health Service

A new book entitled *The National Health Service*, by Dr Charles Hill, secretary of the British Medical Association, and Mr John Woodcock, will be published at 16s by Christopher Johnson, Ltd., at the end of June. The authors expound in simple terms the National Health Service Act and its subordinate legislation, with reference to the Scottish Act where its provisions differ from those of the English Act.

The Osler Club

At the 83rd meeting of the club on May 13 Dr D. Evan Bedford gave an illustrated address entitled "The Ancient Art of Feeling the Pulse." He reviewed the history of pulse taking from the time of the Chinese physicians, who wrote on the subject 2,000 years B.C., to Sir James Mackenzie's work, published at the beginning of this century. He also showed books on this subject from his own library. Mr Geraint Griffith gave a biographical sketch of Sir James Mackenzie, and Mr Peter Thomas spoke on "Inventors of the Sphygmograph." Lord Amulree spoke briefly of Mackenzie, and concluded a most interesting evening by demonstrating his uncle's original together with some of his tracings and notebooks.

Nurses' Pay Increased

Salaries for hospital nurses have been increased with retrospective effect from Feb. 1 as shown in the following tables.

WOMEN

	Previous Annual Rates	New Annual Rates
Ward sister	Cash salary Emoluments £180-260 £120	£375 rising by 7 annual increments of £15 and 1 increment of £20 to £500
Staff nurse	Cash salary Emoluments £140-200 £100	£315 rising by 8 annual increments of £12 10s to £415
Enrolled assistant nurse	Cash salary Emoluments £120-170 £100	£285 rising by 8 annual increments of £12 10s to £385

MEN

	Previous Annual Rates on Non resident Basis	New Annual Rates
Charge nurse	£312-380	£385 rising by 7 annual increments of £15 and 1 increment of £10 to £500
Staff nurse	£260-312	£325 rising by 8 annual increments of £12 10s to £425
Enrolled assistant nurse	£239-291	£300 rising by 8 annual increments of £12 10s to £400

Ward sisters and charge nurses will pay £130 a year (others £120) for board and lodging and other services provided by the hospital. Non resident nurses will pay £20 a year for meals on duty and the use and laundry of uniform.

The Association of the British Pharmaceutical Industry

At the annual dinner of the Association of the British Pharmaceutical Industry, which was held at the Savoy Hotel on April 27, several speakers referred to the need for co-operation between the medical and pharmaceutical professions. In proposing the toast of the Pharmaceutical Services the chairman of the association, Mr C. A. O. Rideal, spoke of the great need for standardization in the pharmaceutical industry. One of the problems was a complicated system of weights and measures, including some peculiarly named containers. The doctors' liking for writing their scripts in Latin was an added difficulty. In reply Dr H. Davis, chief pharmacist to the Ministry of Health, paid tribute to all who had helped to provide the pharmaceutical services of the N.H.S. so successfully up to date. Mr J. C. Hanbury proposed the health of the guests, and said that in facing the problems of the day in the N.H.S. the medical and pharmaceutical professions shared much common ground. Sir Harry Jepcott, in reply, said that the pharmaceutical industry was making every endeavour to co-operate in the steps being taken towards social and industrial progress. Dr D. P. Stevenson, Deputy Secretary of the B.M.A., proposed the toast of the Association of the British Pharmaceutical Industry. Both associations, he said, were quietly performing the task of looking after the interests of the public. This did not stop them from being regarded as Aunt Sallies at times, but nevertheless they had the satisfaction of knowing that in the field of humanity their work was of great importance. The pharmaceutical industry had never failed the medical profession yet. One of the rights which the doctor would always claim for himself was his absolute freedom to prescribe any drug in any form which he felt was needed by his patient. In his reply Mr I. V. L. Ferguson said that for some of the services provided under the N.H.S. the patient had to wait days, weeks, or months, but from the individual doctor and chemist he could always expect to obtain immediate help.

Pharmaceutical School

The Pharmaceutical Society of Great Britain has authorized its council to sell to the University of London for £258,000 the new building going up in Brunswick Square, begun before the war to house the society's college, a school of the University of London, and its other activities. The school, now an independent institution, will occupy the building when completed and the question of the society's own headquarters is under consideration.

Markle Foundation

Thirteen young scientists have been appointed as the second group of scholars in medical science, under the plan begun in 1948 by the John and Mary R. Markle Foundation (14, Wall Street, New York, 5) to assist qualified men and women wishing to remain in academic medicine. The scholars were selected from candidates nominated by accredited medical schools in the United States and Canada. The sum of \$325,000 has been allocated for their support, to be in grants of \$5,000 a year, to cultivate appointments to the British Medical

Register—namely, Dr. John Davis Green, whose interest is in anatomy and physiology, and Dr. Donald Richards Wilson, internal medicine and endocrinology. The grant for Dr. Green has been allotted to the Wayne University College of Medicine, Detroit, and that for Dr. Wilson to the University of Alberta Faculty of Medicine, Edmonton.

Wills

Sir William Hale-White, for many years physician at Guy's Hospital, left £62,920. Dr. John Richard Tarrant Conner, formerly editor of the *Clinical Journal*, left £1,082; Major-General John Weir West, formerly professor of military surgery at the Royal Army Medical School, £4,920; and Dr. Arthur Graham Foljambe Forster, of Cheltenham, £28,036.

COMING EVENTS

Consultants' Meeting at Birmingham

There will be a general meeting of consultants in the Birmingham Region No. 12, at Nuffield House, Queen Elizabeth's Hospital, Birmingham, on Saturday, June 11, at 2.30 p.m., to discuss the proposed terms of service.

Cambridge Graduates' Medical Club

The Cambridge Graduates' Medical Club, which was founded in 1883, will hold its annual dinner at Cambridge in July. The council of the club believes that many Cambridge men who graduated in the war years are unaware of the club's existence, the objects of which are to further the interests of the medical and natural science schools of the University and to promote good fellowship among its graduates. Medically qualified male graduates are eligible for election, the fee for life membership being £1 ls. Those interested should get in touch with their hospital representative or with one of the honorary secretaries, Dr. R. A. Hickling, 99, Harley Street, London, W.1, or Dr. A. Willcox, 66, Harley Street, London, W.1.

SOCIETIES AND LECTURES

Monday

EDINBURGH UNIVERSITY.—At Physiology Lecture Theatre, University New Buildings, Teviot Place, Edinburgh, May 30, 5 p.m., "*Salerno: The First Medical School*," by Dr. Douglas Guthrie.
LONDON UNIVERSITY.—At Institute of Neurology, National Hospital, Queen Square, London, W.C., May 30, 5 p.m., "*Arteriovenous Aneurysms of the Brain*," by Professor H. Olivecrona (Stockholm).
LONDON: UNIVERSITY COLLEGE.—At Physiology Theatre, Gower Street, W.C., May 30, 4.45 p.m., "*Selective Toxicity with Special Reference to Chemotherapy*," by Professor Adrien Albert.

Tuesday

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE.—At Anatomy Lecture Theatre, University New Buildings, May 31, 5 p.m., "*Some Observations on Paroxysmal Tachycardia*," by Dr. I. G. W. Hill.
INSTITUTE OF DERMATOLOGY, 5, Lisle Street, Leicester Square, London, W.C.—May 31, 5 p.m., "*Lupus Erythematosus*," by Dr. H. J. Wallace.
INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., May 31, (1) 11 a.m., "*Aetiology and Diagnosis of Gonorrhoea*," by Dr. W. N. Mascall; (2) 5 p.m., "*Penicillin and Sulphonamide Therapy in Infections of the Urinary Tract*," by Dr. A. H. Harkness.
LONDON: UNIVERSITY COLLEGE.—At Physiology Theatre, Gower Street, W.C., May 31, 5.15 p.m., "*Muscular Contraction*," by Professor A. V. Hill.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—At Royal Society of Medicine, 1, Wimpole Street, London, W., May 31, 5.10 p.m., joint meeting of Society with Section of Experimental Medicine of Royal Society of Medicine. "*Recent Advances in the Study of Venereal Diseases*," by Dr. J. Earle Moore (Baltimore).
WESTMINSTER HOSPITAL SCHOOL OF MEDICINE. Meyerstein Lecture Theatre, Horseferry Road, London, S.W.—May 31, 5.30 p.m., clinicopathological meeting. Discussion: "*Appendicitis*," by Mr. G. T. Mullally.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School, Paddington, W.—May 31, 5 p.m., "*The Nature of Plant Viruses*," by Dr. F. C. Bawden, F.R.S.

Wednesday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., June 1, (1) 11 a.m., "*Signs, Symptoms, and Asymptomatic Carrier State of Gonorrhoea*," by Dr. A. H. Harkness; (2) 5 p.m., "*Congenital Malformations of the Bladder and Urethra*," by Mr. J. E. Semple.

Thursday

CLINICAL SOCIETY OF THE ROYAL FREE HOSPITAL, Gray's Inn Road, London, W.C.—June 2, 5.15 p.m., "*Mammoplasty*," by Dr. Ernesto F. Malbec (Director of Plastic Surgery at Hospital of Ramos Mejia, Buenos Aires). Visitors welcomed.
EDINBURGH UNIVERSITY.—At Anatomy Theatre, University New Buildings, Teviot Place, June 2, 5 p.m., "*Chemotherapy in Reticulositis*," Honynman Gillespie Lecture by Dr. James Innes.

FACULTY OF HOMOEOPATHY.—At Royal London Homoeopathic Hospital, Great Ormond Street, London, W.C., June 2, 5 p.m., "*The Problem of Mental Illness*," by Dr. T. H. B. Gladstone.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., June 2, (1) 11 a.m., "*Pathology of Gonorrhoea*," by Dr. A. H. Harkness; (2) 5 p.m., "*Diseases of the Female Urethra*," by Mr. H. G. Hanley.

LONDON COUNTY MEDICAL SOCIETY.—At Southern Hospital, Dartford, Kent, June 2, 3 p.m., clinical meeting.

LONDON UNIVERSITY.—At Institute of Neurology, National Hospital, Queen Square, London, W.C., June 2, 5 p.m., "*Intermittent Claudication*," by Professor A. M. Boyd.

LONDON: UNIVERSITY COLLEGE.—At Physiology Theatre, Gower Street, W.C., June 2, 4.45 p.m., "*Some Aspects of Nitrogen Metabolism in the Mammal*," by Dr. J. S. Bach.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—June 2, 4.30 p.m., "*Neurology*," lecture-demonstration by Dr. D. J. Williams.

Friday

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—June 3, 8.30 p.m., "*Modern Diagnostic Radiology*," by Dr. G. White Phillips.

APPOINTMENTS

LEWIS, CECIL W. D., M.B., B.Ch., F.R.C.S., Junior Assistant, Surgical Unit, Royal Infirmary, Cardiff.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—*House-surgeon:* Miss J. F. Cambell, M.B., Ch.B. *House-physician:* D. Q. Trounce, M.B., B.S., M.R.C.P., D.C.H. *Registrar to Department of Plastic Surgery:* M. H. Kinmonth, M.B., F.R.C.S.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Brinton.—On May 15, 1949, in London, to the wife of Dr. W. D. Brinton, a daughter.
Fraser.—On May 3, 1949, at Aberdeen, to Dr. Mary E. Fraser (née Chalmers), wife of R. J. A. Fraser, F.R.C.S.Ed., a daughter.
Friedlander.—On May 15, 1949, at Lorna Lodge, 133, Barlow Moor Road, Manchester, 20, to Jean L. Broughton, M.R.C.S., L.R.C.P., wife of H. A. Friedlander, M.R.C.S., L.R.C.P., a daughter.
Lloyd-Owen.—On May 9, 1949, at the Lindo Wing, St. Mary's Hospital, to Helen, wife of Dr. Morus Lloyd-Owen, a daughter.
Macrae.—On April 8, 1949, to Dr. and Mrs. J. O. F. Macrae, Church of Scotland Mission, Ichang, Hupeh, China, a daughter—Gillian Kirsteen.
MacVine.—On April 29, 1949, at the Central Middlesex Hospital, London, N.W., to Daphne (née Vieuzeux), wife of J. Sinclair MacVine, F.R.C.S.Ed., a second daughter—Virginia Anne.
Schorstein.—On May 8, 1949, to Mr. and Mrs. J. Schorstein, of Dumbogoyne Cottage, Dumbogoyne, Stirlingshire, a son.
Smallpeice.—On May 17, 1949, to Olive L. Smallpeice, L.D.S., R.C.S.Eng. (née James), wife of Dr. John Smallpeice, a son.

DEATHS

Atkinson.—On May 7, 1949, Hugh Norman Crowley Atkinson, M.R.C.S., L.R.C.P., of Queniborough, Leicestershire.
Babonau.—On May 9, 1949, at "Ruapuna," Songhor, Kenya, Alexander Frederick Babonau, C.I.E., O.B.E., M.B., Ch.B., Colonel, I.M.S.(ret.).
Bates.—On April 7, 1949, at King George V Hospital, Durban, Robert Fosbrooke Bates, M.B., aged 31.
Brasher.—On May 11, 1949, at St. Leonards, Charles William James Brasher, M.D., aged 83.
Clark.—On May 10, 1949, at Crossways, Brimstage Road, Spital, Bromborough, Cheshire, George Clark, M.B., Ch.B., D.T.M., D.T.H., D.P.H.
Cookson.—On May 15, 1949, at Toronto, Canada, Henry Anstey Cookson, C.B.E., F.R.C.S.Ed., F.R.C.P.Ed., F.R.S.Ed.
Copeman.—On May 6, 1949, at Salisbury Lodge, Hove, Alfred Heathcote Copeman, M.D., aged 80.
Court.—On May 3, 1949, at Raigmore Hospital, Inverness, Edward Percy Court, M.R.C.S., L.R.C.P.
Dalzell.—On May 18, 1949, Philip Dalzell, M.B., B.S., of 1, Raymond Road, Wimbledon, London, S.W., aged 43.
Davidson.—On May 7, 1949, at Woodville, Shettleston Road, Glasgow, E.2, William Tennent Gairdner Davidson, M.D., D.P.H.
Edleston.—On May 8, 1949, at The Mount, Hatherton, Nantwich, Richard Shafto Chambers Edleston, M.R.C.S., L.R.C.P.
Goss.—On May 12, 1949, at R.N. Hospital, Plymouth, Leslie Stewart Goss, O.B.E., L.M.S.S.A., Surgeon-Captain R.N. Ret.
Hoffman.—On May 17, 1949, at Axminster Cottage Hospital, Harry Drummond Hoffman, M.B., aged 72.
Leicester.—On May 19, 1949, at Clare Cottage, Cold Ash, Newbury, Berks, John Cyril Holdich Leicester, M.D., F.R.C.P., F.R.C.S., Lieutenant-Colonel, I.M.S.(ret.), aged 77.
Mackay.—On May 8, 1949, at 9, Belford Avenue, Edinburgh, George Mackay, M.D., F.R.C.S.Ed.
McKee.—On May 7, 1949, at St. Mary's Bay, Kent, William Cowan McKee, M.B., B.Ch., Lieutenant-Colonel I.M.S. retired.
Mackie.—On May 8, 1949, at a nursing home, Edinburgh, Elspeth MacLeod, M.B., Ch.B., wife of F. J. B. Mackie, 1, McLaren Road, Edinburgh.
MacLagan.—On May 8, 1949, at Kello Hospital, Biggar, Lanarkshire, Patrick Alexander MacLagan, M.B., Ch.B.Ed.
Macnaughton-Jones.—On May 15, 1949, at Amersham, Henry Macnaughton-Jones, M.B., B.Ch., aged 80.
Martin.—On May 22, 1949, at 10, York Gate, London, N.W.1, Ernest William Martin, M.B., Ch.B., aged 72.
Mariland.—On May 16, 1949, at a nursing-home near Darlington, William Lionel Mariland, M.B., Ch.B., aged 50.
Menzies.—On May 14, 1949, at 41, Melbury Court, London, W., Sir Frederick Norton Kay Menzies, K.B.E., M.D., F.R.C.P., aged 73.
Phipps.—On May 14, 1949, Forster, Cawsand, H. H. Phipps, M.R.C.S., L.R.C.P., aged 85.
Rogers.—On May 14, 1949, at Namouna, West Cliff Road, Bournemouth, Kenneth Rogers, O.B.E., M.D.
Williams.—On May 12, 1949, at Liverpool, David Llewelyn Williams, C.B.E., M.C., LL.D., F.R.C.S.Ed., aged 79.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Treatment of Osteoarthritis

Q.—What is the usual modern treatment for osteoarthritis of the knee-joint?

A.—The treatment of osteoarthritis of the knee-joint may be non-surgical or surgical.

Non-surgical Treatment.—It should be appreciated that the joint changes of osteoarthritis are permanent, and treatment can be only palliative. The following measures are available, and each has its indications: (1) Rest.—This will always lead to improvement in the symptoms. In some cases avoidance of prolonged standing or walking is all that is required. In the occasional case, particularly after recent injury or when there is some degree of fixed flexion deformity, temporary immobilization in plaster—if necessary after gentle straightening of the knee—is of value. (2) Physiotherapy.—The most effective form of physiotherapy is a combination of short-wave diathermy with intensive active exercises designed to improve the muscle control of the knee. In cases of moderate severity this often gives satisfactory relief, and it is probably the most widely applicable method of conservative treatment. (3) Acid Injections.—10 to 20 ml. of acid potassium phosphate or other appropriate acid solution—often combined with procaine—is injected into the joint. A course of treatment commonly consists of six to twelve injections at weekly intervals. The method is still on trial; while improvement has been claimed by a number of workers, there is probably a majority of orthopaedic surgeons who feel that its value is very doubtful. (4) X-ray Therapy.—Improvement has been obtained, but not constantly. This treatment should be tried only when other measures have failed to secure adequate relief.

Surgical Treatment.—Operative measures are not often required, though in the occasional case with severe disablement the result may be eminently satisfactory to the patient. (1) Excision of the patella is indicated in certain cases where the arthritic process is confined to the patello-femoral compartment—particularly after malunited fractures of the patella with distortion of its articular surface; but it is unlikely to be of benefit when the arthritis has reached an advanced stage. (2) Arthrodesis is advised only when pain or deformity is causing such a severe degree of crippling that a stiff knee becomes acceptable to the patient. In cases of this severe type—where degenerative arthritis is often secondary to a previously existing infective arthritis—the results of arthrodesis are often very satisfactory, sometimes even in bilateral cases. (3) Arthroplasty gives such inconsistent results that it is indicated only exceptionally, if at all. It is possible that in the future improved methods of performing the operation may increase its usefulness.

Post-gastrectomy Diet

Q.—What diet and what medicine should be prescribed for a patient who has just had a partial gastrectomy?

A.—It is assumed that the question does not refer to the immediate post-operative period but to the time, 14 to 21 days after operation, when the patient is beginning to lead an active life again. At this stage the usual type of "post-Lehnhart" diet is suitable; meals should be frequent, regularly spaced, and small in bulk. Gradually the volume of individual meals may be increased and the interval between them lengthened until only four are taken daily. Their composition should be bland at first, but over two or three months more dishes can be added until a virtually normal diet is being taken. Most patients who have undergone partial gastrectomy are eating normally two or three months after operation. There is no general indication for medicines, but in some instances a vitamin concentrate and iron may be advisable.

Threadworms

Q.—Would you please tell me the dose and the method of administration of carbon tetrachloride followed by saline purgation for a child of 7 and her mother? Is this treatment for threadworms always successful, and, if not, how soon can it be repeated?

A.—Carbon tetrachloride is highly toxic and possesses few advantages over the less toxic and almost as effective anthelmintic tetrachlorethylene, but it is doubtful if either treatment should be given unless the patient is in hospital. The oral dose advised for tetrachlorethylene is 3 ml. (in three 1-ml. soft gelatin capsules) for an adult, and 3 minims (0.18 ml.) per year of age for a child. Alcohol and all fats, including milk, should be withheld for two days previous to giving the drug, which should be administered before food is taken on the morning after a saline purge has been given. The patient should remain in bed throughout the treatment. In cases of failure treatment should not be repeated until three weeks have elapsed.

An alternative treatment is with hexylresorcinol orally combined with enemas. The dose is 1 g. for adults and for children over 10 years; below 10, for each year of age 0.1 g. The drug should be administered in hard gelatin capsules. If the oral dose is taken in the morning, a soap-sud enema should be given the same evening, to be followed by another enema of a 0.1% solution of hexylresorcinol crystals in water, which should be retained for fifteen minutes. The treatment of threadworms, particularly in children, has been fully investigated by Wright and his colleagues in America, and the results of their investigations have been published in a series of articles. After trying many lines of treatment they consider that the one yielding the best results with the minimum of risk is the administration of gentian violet. The method of administration and the preparation of the patient are fully described in a paper which appeared in the *Journal of the American Medical Association* (1940, 114, 861). No known form of treatment is always successful.

Effect of Mandelic Acid

Q.—Are any ill effects likely to result from taking mandelic acid over long periods?

A.—No ill effects are to be expected from taking mandelic acid over long periods. Mandelic acid is a fatty acid which is excreted unchanged. However, when it is taken, it is usually given as ammonium mandelate or calcium mandelate, and in this form it produces an acid urine, which is necessary if it is to be effective bactericidally. The maintenance of an acid urine for long periods may be harmful in persons suffering from some degree of renal damage; this may be further aggravated by restriction of the fluid intake. To maintain full treatment with fluid restricted to 2 pints (1,136.5 ml.) and a urine of acidity pH 5.5 is often very depressing for the patient.

Green Staining of Hair

Q.—It has been suggested that an impregnating varnish consisting of an oil-modified phenolic resin dissolved in white spirit might be the cause of the green staining of the hair which occurs in men with white hair who come into contact with it in a factory. As the discoloration is confined to the front of the hair, it is probably connected with perspiration. Could you give any information, with references, on pigmentation of the hair which would help in tracing the source of the trouble?

A.—The inquirer does not give sufficient data to enable fair comment to be made. It would be helpful to have been told if copper is actually handled by the affected workers or is present in the shops as dust; if the staining washes out with soap and water; and the colour of the varnish. It seems unlikely that the varnish, unless it is actually green in colour and is carelessly handled by the workers, is the cause of the green pigmentation of the hair.

Copper has been known to cause green staining of the hair and perspiration. Flinn and Inouye (*J. biol. Chem.*, 1929, 84, 107) refer to the statement in the literature that "copper dust, or alloys rich in copper, generally produce in workers green-stained hair, greenish deposits on the teeth, and a green tint to the perspiration which may persist even after a thorough bath, while the skin may be actually bronzed." Mallory (*Arch. intern. Med.*, 1926, 37, 336) states that continued exposure to

copper, such as is experienced by workers in copper foundries, will cause haematochromatosis. I. J. Cunningham (*Biochem. J.*, 1931, 25, 1273) remarks on the catalytic effect of copper on the oxidation of "dopa" (3:4-dihydroxyphenylalanine), which is the precursor of melanin, the pigment in hair. Copper and its effect on health is discussed in *Industrial Medicine*, 1947, 16, 368. A detailed discussion on hair-colour change can be found in *J. Amer. med. Ass.*, 1943, 121, 161.

Malignant Deposit in Pelvis

Q.—For the last year a woman of 51 who had a carcinoma of the breast removed three years ago has been having back-ache, never localized, but most frequently in the lumbar region. X-ray examination reveals an osteoarthritis of the spine; there is also a "spot" in the pelvis which may indicate the presence of malignant deposits. A blood examination shows her alkaline phosphatase level to be 5 units per 100 ml.—this, I am told, does not support a diagnosis of malignancy. Would you please give your view?

A.—Osseous metastases during the early phase of their development give rise to indefinite signs on radiological examination, and in such cases repeated radiography at monthly intervals is of value. Estimations of the alkaline phosphatase concentration in the blood are of limited value. It is true that in some cases of osseous metastases the figure is raised, but it may be normal, and conditions other than this may cause changes in the alkaline phosphatase level. This patient should be kept under careful observation and further radiological examinations of the pelvis carried out at intervals.

Blood Transfusion in CO Poisoning

Q.—Has replacement blood transfusion ever been tried in cases of coal-gas poisoning? Six to eight pints (3.4 to 4.5 litres) would seem to be enough if the patient is in real danger.

A.—Blood transfusion has been used in the treatment of carbon-monoxide poisoning. Special care must be exercised to ensure that the circulation is not overloaded, because such overloading would have serious, and very possibly fatal, effects on a heart already dilated and weakened by anoxia. The method adopted must therefore be one of replacement, as the question suggests, but the quantities mentioned are excessive. Blood transfusion should not be regarded as a routine requirement in cases of coal-gas poisoning. Most of the patients reaching hospital alive will have eliminated a considerable proportion of the carbon monoxide, and other lines of treatment, such as the administration of oxygen with carbon dioxide, will give satisfactory results in the majority of cases.

Allergy to Animal Fat

Q.—Is it possible to desensitize a patient who is allergic to animal fats? He is unable to eat an average amount of animal fat without developing small pustules on his chin; this also occurs after shaving with soap containing such fat. He is not allergic to vegetable fats.

A.—Desensitization to a food is of doubtful value and is rarely advisable. The best treatment is its complete avoidance, when the hypersensitivity is frequently outgrown. It is most unusual for a person to be allergic to all animal fats, nor are pustules a common manifestation of spontaneous allergy. More usually the sensitivity is to the products of individual species of animal.

Penile Herpes or Verrucae

Q.—A young man aged 24, with no history or signs of specific venereal infection, has developed a chain of papilla-like processes about the size of a pin's head in the coronal sulcus. These bodies do not resemble venereal warts; there is no phimosis and no other evidence of balanitis. Applications of glacial acetic acid caused temporary "whitening" of these papillae, but they have not disappeared. What alternative treatment would you suggest? Is the condition progressive, and are any serious sequelae likely in the patient or his wife?

A.—From the information given, the lesions appear to be either herpes or verrucae—probably the former. Unless they are giving rise to unpleasant symptoms, no treatment is indicated; should treatment be deemed advisable, keeping the parts dry and powdering with talcum are recommended. Such

methods as circumcision, excision of the affected epithelium, or destruction with the electrocautery are unnecessarily drastic and are contraindicated. For warts such as are commonly seen in connexion with a chronic urethritis, podophyllin resin B.P. 25% or less in liquid paraffin is remarkably successful; the surrounding parts should be protected with a film of petroleum jelly and the podophyllin applied with a swab and allowed to dry; if necessary, a second application may be made after a few days.

The condition described is not likely to be progressive, though it may take a considerable time to clear up; nor is it likely to cause any serious sequelae in either the patient or his wife.

Transient Giddiness

Q.—What are the causes and treatment of momentary transient vertigo? I have many patients—non-smokers, non-drinkers, with normal blood pressures, and aged 40 to 60—who complain of momentary giddiness after stooping, on looking up to the sky, or on rotating the head.

A.—Probably some of these are not cases of true vertigo. Thus, momentary dizziness after stooping is often caused by a temporary cerebral anaemia due to poor vascular tone, and the subject should derive benefit from physical exercises, particularly for the abdominal muscles. The other cases are probably due to abnormal proprioceptive or ocular impulses. Thus rheumatic affections of the cervical joints and muscles may be a factor. In the ocular cases, or in those with true postural vertigo, phenobarbitone or other sedatives should help.

NOTES AND COMMENTS

Keloid.—Dr. F. PIERS (Nairobi) writes: A correspondent asked which was the best treatment for keloids ("Any Questions?" Feb. 26, p. 377). Your expert, in his reply, advised x-ray treatment and excision of the scar. With great respect I beg to disagree with him, especially as regards excision. Keloids invariably recur and assume a more unpleasant character after surgical interference. I have recently seen a young Greek woman from Abyssinia who had originally, a small keloid over the sternal region. This was twice excised by competent Italian surgeons, and each time the result had been a more extensive and unsightly recurrence of the keloid. The method of choice is, in my opinion, radium treatment: repeated surface applications with heavy filters (to exclude all but the hardest beta radiation). A report of two cases in which this method gave excellent results was published by W. Lutz (*Dermatologica*, 1947, 94, 315). The pictures accompanying the article supply convincing evidence of the value of this method.

Corrections

In the leading article on "Diphtheria Prophylactics," which was published in the *Journal* of April 23, p. 715, it was stated that the number of notified cases of diphtheria in 1947 was 3,941 and 0 deaths 198. These figures, however, relate to children under 14 only. The figures for the whole population, obtained from the quarterly returns (corrected notifications) issued by the Registrar General, are 5,609 cases of diphtheria notified in 1947 and 24 deaths.

Dr. D. DAVIES writes: In my paper on "Acute Porphyria and Associated Electrolyte Changes" (May 14, p. 846) in the fourth paragraph "chronic porphyria" should have read "congenita porphyria."

Dr. JAMES OVERTON writes: In my recent article on the topic use of "vioform" in dermatology (May 14, p. 840), an error has been brought to my notice. In the first paragraph on p. 841, dealing with the pharmacology, "In vitro it inhibits *Staph. aureus* and *Bact. coli* in a dilution of 0.025%," should have read "0.025% 'vioform' in bouillon." This is another method of stating 0.02 parts per thousand.

SUPPLEMENT TO THE BRITISH MEDICAL JOURNAL

LONDON SATURDAY MAY 28 1949

THE SECRETARY REPORTS

CHANGES IN SUPERANNUATION

uperannuation is a somewhat dusty and complicated topic, but to those who see daylight—as well as eventide—in the superannuation provisions a note on some contemplated changes may be of interest. There has been published a draft of amending regulations which the Minister proposes to make, and the amendments include a number of points of interest to the profession. It will be recalled that general practitioners who entered the list of an executive council on or before July 5, 1948, and who had already made provision for retirement by endowment or deferred annuity policies were given the option to remain outside the Government superannuation scheme and to receive from the Ministry an amount equivalent to the employer's contribution (8% of net remuneration) towards the payment of their policy premiums. This option was limited to medical and dental practitioners (and their assistants) on executive council lists.

In the proposed amending regulations the option is extended to "persons rendering specialist services pursuant to Section 3 of the Act." This means that a specialist in contract with a regional hospital board or board of governors will be entitled to apply to the Minister to be excluded from the superannuation scheme and to receive the equivalent of the Government's contribution towards the continuance of a private insurance policy. Specialist services are not defined in the Act, but it seems that the extension of the option will be limited to those who are appointed as specialists, as distinct from those holding non-specialist posts.

The conditions governing the option under the original regulations were as follows:

(a) The policies must be endowment assurances or deferred annuity policies.

(b) The policies must not mature at an earlier age than 60. Where a policy would under its original terms have matured before age 60, it can be recognized if its terms are modified so that it matures at or after age 60.

(c) (i) The premiums (or total premiums) must not be less than £150 per annum.

(c) (ii) Alternatively, if the total annual premiums on existing policies are less than £150 per annum but not less than £50 per annum, these policies will be recognized on condition that the practitioner takes out forthwith a further policy which will bring the total premiums to at least £150 per annum on policies satisfying the conditions set out in (a) and (b) above.

(d) The policies must not be assigned to any other person, or surrendered before maturity.

(e) Payment by the Minister of an amount equal to 8% of the practitioner's remuneration will continue only so long as he premiums on the policies continue to be payable.

(f) The policies must be produced for inspection on a request made to the practitioner by the Minister or by the executive council on his behalf. Alternatively, a statement from the insurance company as to the nature of the policies may be submitted.

(g) Premium receipts must be submitted to the Minister or to the executive council for examination within one month after the date on which each payment of premium falls due.

It is probable that similar conditions will apply to specialists, with the substitution of "regional hospital board or board of governors" for "executive council" in paragraphs (f) and (g).

Another important provision concerns specialists who continue to work after the normal retiring age of 65. Representations were made to the Ministry that in such cases the specialist should be able to continue to pay contributions and to build up further pension. The Ministry proposes to vary the original regulation to enable practitioners to earn another five years' pension reckoning above the normal maximum of 40 years. For this purpose "pensionable age" is increased by five years and the maximum amount of a pension is increased from 40/80ths to 45/80ths in the case of practitioners on a whole-time salaried basis, and, in the cases of general practitioners—and part-time specialists—on the 1½% basis, the period reckonable is increased from 40 years to 45 years. In other words, instead of the G.P. pension being based on 1½% of the total net remuneration received throughout 40 years of service, it will be based on 1½% of the total net remuneration received throughout 45 years of service.

Theoretically, the right to reckon 45 years' service is a valuable extension of the 40-year maximum which has been a prominent feature of previous superannuation codes. But in the case of medical practitioners who, by reason of the long years spent in qualifying, are unable to enter the Service until 25 or more years of age, few will be able to attain the maximum pension. The new provision, however, will enable those who do carry on until aged 70 to count those later years for an increase in pensions.

Town and Country Planning Act, 1947

This Act imposes a development charge, which will be assessed by and be payable to the Central Land Board, wherever development improves the value of land. "Development" includes a material change of use of the land or of any buildings on it. The State has set aside a sum of £300 million for the compensation of those owning or leasing property on July 1, 1948, the value of which is substantially reduced by the Act. The underlying principle of the Act is that all land in future, when bought or sold, should pass at a price equal to its value for existing use. Broadly, the development charge will be the difference between the value for the existing use and the value when the permitted development has taken place. Claims for the loss of development value in consequence of the Act must be in the hands of the Board by June 30, 1949. A further note on the implications of the Act, with special reference to the position of members of the profession, will appear in these columns next week.

The Grading of Hospital Staffs

A good number of letters are reaching this office from practitioners who object to the grading proposed for them on the recommendation of Review Committees. The bulk of the letters come from members of hospital staffs who find themselves graded, not as specialists, but as senior hospital officers. In many cases hospital staffs who have regarded themselves as equals for many years now find that they are being graded unequally. The Joint Committee is continuing to press for a proper appeal machinery, and in the meantime any practitioner who objects to his grading should communicate at once with the regional hospital board or board of governors concerned.

National Health Service

HEARD AT HEADQUARTERS

CHANGES OF HOSPITAL STAFF

MINISTER'S OBLIGATION

The Ministry of Health has informed hospital boards that the Minister has a moral obligation for seeing that displaced members of staffs are given, so far as is practicable, the opportunity of undertaking similar duties elsewhere. This move follows representations made by the Joint Committee of Consultants and Specialists.

Displacement or serious disturbance may occur where the board proposes to change the use of particular premises or to carry out the work with fewer staff. The Minister considers that regional hospital boards should be able in almost every case to arrange for the displaced specialists to be offered duties of similar scope and extent in some other hospital. It is more difficult for boards of governors to do this, because their administrative control is over a much narrower field, but they should seek the co-operation of neighbouring regional hospital boards, and he asks the regional boards to do all they can to help.

The Minister's obligation was affirmed in one of the replies that he gave in April, 1948, to the B.M.A. Questionary (*Journal*, April 17, 1948, p. 742): After the appointed day "it will be the duty of the boards to review the specialist services of their regions, and they will offer new appointments to their staffs either in their existing or other hospitals, which they will be free to accept or refuse as they will."

DENTISTS' FEES

20 % CUT PROPOSED

The Minister of Health proposes to cut the gross fees of dentists by about 20% from June 1. He has prepared a new scale in detail of reduced fees for dental examinations and operations. The Ministry has analysed the earnings of 5,078 dentists from October, 1948, to March, 1949. The figures in the following table show the annual rate of payment based on this analysis, and do not take account of the cut of 50% in dental earnings over a rate of £400 monthly which was imposed in February, and do not make allowance for superannuation.

No. of Dentists	Range of Gross Earnings	Range of Net Earnings (Assuming 52% Practice Expenses)
209	£ 0-1,200	£ 0-576
712	1,201-2,400	577-1,152
1,128	2,401-3,600	1,153-1,728
1,122	3,601-4,800	1,729-2,304
841	4,801-6,000	2,305-2,880
479	6,001-7,200	2,881-3,456
254	7,201-8,400	3,457-4,032
333	Over 8,400	Over 4,032

The original fees for dentists were devised to fulfil the Spens Committee's recommendations on the basis of 33 chairside hours a week being worked. In February the Minister considered that some dentists were earning excessive fees, and he therefore halved the amount that could be earned over the maximum of £4,800 a year. It seems questionable whether the present reductions, which will affect the earnings of all dentists, will enable the Spens recommendations to be implemented, since one of those recommendations was that the optimum chairside hours that a dentist should work was 33 a week. It would appear that dentists may now have to work more hours if their incomes are to conform with the other Spens recommendations.

Meanwhile a working party set up by the Minister is investigating the timing of dental operations. The British Dental Association announces that such arbitrary reductions "demonstrate the essential unsoundness of the dental scheme." The association would prefer grants to be paid towards the fees, the latter being agreed between the patient and the dentist.

Mr. Bevan with the Midwives

The midwives did not "boo" Mr. Bevan, as some of the newspapers said, when he addressed them the other day. Their exclamations were rather directed against the doctor Mr. Bevan, who, by the way, was careful throughout to speak of "general-practitioner obstetricians," not "general practitioners," said that the woman who had made an arrangement with the general-practitioner obstetrician would look to him for his share of antenatal and post-natal care and for attendance at confinement if, and only if, he thought this necessary. This statement called forth a derisive chorus of "He! The woman, Mr. Bevan said, would still require the service of a midwife, who would carry out her share of maternity work and normally conduct the confinement, calling in the general-practitioner obstetrician in case of need. His statement that the midwives suffered no loss of professional status was greeted with loud expressions of scepticism, and Mr. Bevan went on, "I hope the doctors are listening to this. The doctor who will be called in in case of need will be one already acquainted with the patient and may well be her own family doctor." He repeated that it was never the intention of the Government that any development of the National Health Service Act should denigrate—his own word—the status of the midwife. The development of the general-practitioner obstetrician scheme, in which he himself had taken a keen personal interest, was never intended to do more than provide by the side of the midwife a local pool of skilled obstetrical knowledge available to her when she wanted it. "But they are all in the pool," cried the midwife. Mr. Bevan said that if that was so it was an abuse of the scheme.

Literary Doctors

A departure was made this year in the Cavendish Lecture delivered before the West London Medico-Chirurgical Society in that, for the first time in its long history, it had nothing to do with medicine. Mr. Justice Birkett was the lecturer, and addressed the company on the contribution of lawyers to literature. Henry Cavendish, whose name the lecture bears, had no particular interest in either law or literature, but for that matter he had no particular interest in medicine either, being a chemist and a philosopher. The proposer of the vote of thanks to Mr. Justice Birkett took occasion to remark that the medical as well as the legal profession had made great contributions to literature, and he mentioned a string of names—Sir Thomas Browne, Oliver Goldsmith, John Keats, Oliver Wendell Holmes, Robert Bridges, Conan Doyle, A. J. Cronin, Brett Young, Somerset Maugham. Sir Norman Birkett, in reply, said that he was astonished that from this list the greatest name of all had been omitted—St. Luke, the beloved physician. "Your profession is more beloved than mine," he went on. "The word 'beloved physician' have a most appropriate ring, but it would come as a great shock to me to hear in common use the word 'beloved lawyer.'"

International Relations

The international affiliations of the Association are increasing. The Council is to give a dinner in the Great Hall to the delegates to the General Assembly of the World Medical Association in October. In the earlier years of occupancy in Tavistock Square several dinners were given in the Great Hall, and was generally felt that there was some special advantage in the Association entertaining its guests in its own home. In addition there will be an afternoon reception at B.M.A. House in July for the Commonwealth and Empire Health and Tuberculosis Conference. The International Relations Committee is to consider at the beginning of each year the occasions on which receptions may be given to visiting congresses. An advisory bureau for foreign medical visitors on the lines of the Empire Medical Advisory Bureau is also projected.

Relief

CROOKES IODINE OIL retains the full therapeutic activity and does not exhibit the disagreeable side-effects of the familiar pharmaceutical iodine products.

Marked relief of symptoms has followed its use in cases of fibrositis and muscular rheumatism. Beneficial results have been reported in the treatment of fungoid infections including ringworm and perionychia

As a local application Crookes Iodine Oil is particularly effective in restoring to normal sprained joints and muscles weak from disuse following the treatment of fractures and other causes.

THE CROOKES LABORATORIES LIMITED · PARK ROYAL · LONDON · N.W.10

for the

treatment of
HAYFEVER

'Benadryl'

It has been found possible to control the symptoms of hay fever in many patients by the oral administration of 'Benadryl'. This potent histamine antagonist is also invaluable for those who have not had time to acquire complete tolerance to grass pollen after desensitizing courses with pollen extract.

One 50 mgm. capsule of 'Benadryl' taken when hay fever symptoms first appear often gives relief for from three to five hours. Subsequent dosage depends on the response of the patient and on the prevailing atmospheric conditions. For infants and children, Elixir 'Benadryl' or 25 mgm. capsules are available.

Capsules: (25 and 50 mgm.) in bottles of 50 and 500.
Elixir: In bottles of 4 and 16 fluid ounces.

Failing
appetite . . .

OFTEN of nervous or irritable disposition the patient who is unable to define his symptoms clearly may speak of poor appetite, lack of energy, or loss of weight. These symptoms frequently portray the early stages of sub-clinical vitamin B deficiency.

It has been shown that where the deficiency of one factor exists there is a need for the total B complex. 'Beplex' Elixir, an extract of rice bran with added thiamine and riboflavin, contains all the known factors of the B complex and enables adequate amounts to be given in a small dose.

'Beplex' is also available in capsule form.

BEPLEX Elixir

Each 10 c.c. of Elixir contains: Thiamin Hydrochloride 125 mg. Riboflavin 250 mg. Niacin 1 250 mg. Pyridoxine Hydrochloride 125 mg. d pantothenic acid 625 mg. and other B complex factors

JOHN WYETH & BROTHER LIMITED
Clifton House, Euston Road, London, N.W.1
ALUDROX - ENDRINE - PETROLAGAR - PLASTULES

The HECSO^N SUPER ELASTIC TRUSS for the Treatment of Hernia

Strap is fixed to Pad at A. Therefore greater pressure is exerted at B, when the strap is pulled tightly.

Where treatment of Hernia by surgical methods is undesirable for any reasons, the HECSON super elastic truss can be confidently recommended. The Special Feature of the HECSON Truss is that the perineal or under strap is attached to the top of the pad instead of the lower margin as in the ordinary elastic or old spring truss. Thus it becomes part of the leverage mechanism for increasing the pressure of the pad at its base.

Price : Single £2 12s. 6d.
Double £3 13s. 6d.

PRELIMINARY

Annual Meeting, 1950

172. The Council has gratefully accepted an invitation from the Liverpool and Southport Divisions to the Association to hold the Annual Meeting in 1950 at Liverpool and Southport. The meeting will be held from July 21-29.

The Council recommends:

Recommendation: That Professor T. P. McMurray, C.B.E., M.Ch., F.R.C.S.Ed., be elected as President of the Association, 1950-1.

Representation of Medical Branch, Royal Navy, on the Council

173. The Council recommends:

Recommendation: That Surgeon Rear-Admiral C. H. M. Gimlette, R.N.Ret., be elected as the representative of the Medical Branch, Royal Navy, on the Council for the period 1949-52.

Centenary Celebrations of Netherlands Medical Association

174. The Netherlands Medical Association celebrates its centenary at Amsterdam in July, and the Association was invited to appoint a delegate to attend. The Council appointed Dr. O. C. Carter to act in this capacity.

Medical Society of the Hospitals of Paris

175. Mr. R. L. Newell has been appointed by the Council to attend the centenary celebrations of the Medical Society of the Hospitals of Paris in October.

Portrait of Dr. H. Guy Dain

176. The Council is making arrangements for the painting of a portrait of the Chairman of Council.

NATIONAL HEALTH SERVICE

The Amending Bill

177. The National Health Service (Amendment) Bill was presented to the House of Commons on May 11, 1949. The content of the Bill was not discussed before publication of the Bill with representatives of the profession, as was promised, and a strong protest has been made to the Ministry. Discussions with the Ministry have begun and all possible steps will be taken to extend the scope of the Amending Bill to include a number of points put forward by the profession.

The Bill, which was published in the *Journal (Supplement, May 21, p. 274)*, gives effect to the recommendations of the

Legal Committee on Partnerships; prohibits a full-time salaried general-practitioner service (with an exception for "special circumstances"); precludes the imposition by regulations of any universal whole-time specialist service; gives executive councils the right to select their own chairman and to determine his term of office; provides for the professional member of the tribunal to be selected from a panel of available members, and empowers executive councils, on the request of the local medical, dental, or pharmaceutical committee, to make deductions from the remuneration of doctors, dentists, or chemists to defray the administrative expenses of those local professional committees.

In addition to these points, provision for which had been promised by the Minister, the Bill contains certain other proposals, among which may be mentioned:

(1) Clarification of the position obtaining under agreements between principals and assistants. The Legal Committee on Partnerships made no recommendation on this point, but expressed the view that the relationship between principal and assistant seemed to be analogous to that of partners, adding that "it would seem that the Act may cause considerable hardship to such assistants if no protection is afforded."

(2) Under Section 12 of the Amending Bill any difference or dispute arising in respect of remuneration or conditions of service of those employed or engaged in the new Service is deemed to be a trade dispute within the meaning of the Industrial Courts Act, 1919, and to be a difference or dispute to which the Conciliation Act, 1896, applies. In effect this means that, where a dispute exists or is apprehended, either party may report it to the Minister of Labour and National Service and he may refer it, if both parties consent, to an industrial court for settlement. On the other hand, if both parties do not consent, he may refer it to the industrial court for advice. The composition of the industrial court is prescribed by the 1919 Act. The Minister of Labour and National Service appoints an independent president or chairman and also appoints a panel of other persons, some independent and others representing employers and workers respectively, to be members of the court. The members to sit as the court on any particular occasion are selected from this panel by the president.

This proposal deserves careful scrutiny. At first sight it seems that only where the Minister agrees can arbitration take place, and where he does not so agree all that can happen is that an outside body, set up for the purpose, gives advice. This appears to fall short of the original Whitley proposal that in the event of disagreement being registered recourse could be had to arbitration whether the other side agreed or not.

(3) The omission in the original Acts of any provision for the removal from the lists of executive councils of doctors, dentists, or chemists who have ceased to provide services in the areas concerned is rectified.

(4) The extension from two months to three months of the period within which doctors called in by midwives under the Midwives Act, 1918, are required to submit their account to the local supervising authority for payment. For many years the profession has been seeking an extension of the two-months time limit.

With the exception of these last two items (3 and 4) none of the additional points which have been pressed upon the Ministry by the General Medical Services Committee and by the Joint Committee for Consultants and Specialists were included in the Bill.

General-practitioner Remuneration

Reference is made in the General Medical Services Committee's section of this Report to the delay in dealing with the General Medical Services Committee's representations for an increase in the Central Practitioners Fund in the light of the report of expert economists on the betterment factor which should be applied to the Spens recommendations to convert them to present-day values.

The General Medical Services Committee has asked for an interview with the Minister himself with a view to expediting a settlement of the Committee's claim.

The Joint Committee for Consultants

The Joint Committee of the Royal Colleges, the Scottish Royal Corporations, and the Central Consultants and Specialists Committee submitted to the Ministry early in May a statement of the considered views of its constituent bodies on the proposed terms and conditions of service for hospital medical and dental staff. During the last week in May discussions opened between the Joint Committee and representatives of the Ministry, and a report of developments in the light of these discussions will be submitted to the constituent bodies in due course.

GENERAL MEDICAL SERVICES

Remuneration

178. The memorandum (*B.M.J. Supplement*, Feb. 19) approved by the Special Conference and Special Representative Meeting in March was sent to the Ministry of Health on March 4. At an interview with officers of the Ministry on April 14 it was learned that the Ministry had decided that insufficient information was available on which to assess how far the Spens recommendations were being implemented. The main factors were the number of doctors in the Service and the total amount each doctor was receiving from N.H.S. funds. Neither of these factors was known to the Ministry with any degree of precision, and a national inquiry had been instituted, from the result of which it was anticipated definite conclusions could be drawn. The Ministry hoped the result of its inquiry would be available within a month, when its representatives would be in a better position to discuss the profession's claim for an increase in the Central Pool.

Two disturbing features of the interview referred to above were, first, an indication by the Ministry's representatives that there could be no assurance that any improvement in the remuneration of general practitioners which might emerge from negotiations would be applied retrospectively to July 5, 1948. Secondly, when asked what the position would be if, having raised the question of general-practitioner remuneration through Whitley machinery and, in the event of disagreement, the profession's representatives sought arbitration, the reply given was: "It must not be assumed without further discussion that participation in the Whitley machinery necessarily involves, in the event of disagreement, the right to resort compulsorily to arbitration on all subjects."

The Ministry's representatives were informed that the statements on these two points were very unsatisfactory. It was regarded as unreasonable to inform the profession that it might not receive any increase in the "pool" retrospectively to July, 1948. The Ministry received ample notice of the profession's intention to raise the question of "betterment," and the profession was entitled to arrears of payment on this issue and on any increase in the number of general practitioners in the Service over and above the number (17,900) which was a factor in calculating the Central Pool before the appointed day.

On the question of arbitration it was pointed out that the Ministry's statement was in conflict with repeated assurance given by Ministers, both in Parliament and personally, representatives of the profession.

It has been decided that no positive action can usefully be taken until the result of the inquiry undertaken by the Ministry is available. It was felt, however, to be necessary to place on record the profession's dissatisfaction with certain statements made to its representatives, and the following resolutions of the General Medical Services Committee of the Association were sent to the Ministry:

"That the committee records its dissatisfaction with the Ministry inability to state, nine months after the appointed day, the number of principals taking part in the Service, and with the statement that in so far as the Central Pool may prove to have been inadequate for the first nine months of the Service, any increase may not be adjusted retrospectively to the appointed day.

"That, in view of the statements made by responsible Ministers prior to the appointed day, the committee is of opinion that the Ministry's view that disputes concerning remuneration referred through Whitley machinery do not carry the right to arbitration on either side is a gross breach of faith."

(See also paragraph 177 of this report.)

Volume of Work Done by General Practitioners

179. A statistical inquiry into the volume of work done by general practitioners, covering a period of one year, is to be undertaken in the near future.

Mileage

180. The resolutions of the Special Representative Meeting in March on the adequacy of the present mileage grant have been considered, and as a first step an inquiry has been instituted for the purpose of showing, by comparison with the position which existed under the N.H.I. Act, the increase in the total number of patients in respect of whom mileage was claimed, the number of doctors claiming mileage, and the total number of mileage units claimed. Proposals for dealing with claims for special difficulties, such as footpaths under winter conditions, are also under consideration.

The existing mileage grant covers mileage for attendance on maternity cases, and it is proposed that a practitioner practising in an area where a mileage scheme normally operates, whether or not he is on the Obstetric List, shall be entitled to a single payment for each maternity case booked at the rate of 3s. per mile (outward) over two miles from the practitioner's residence to the patient's address.

Training of Assistants

181. The scheme for providing grants for training assistant has been examined with the object of suggesting improvement. The general conclusion reached is that the scheme as at present designed is primarily for the benefit of the trainee and should be regarded as such. Any financial benefit which the principal may hope to derive from the help given by assistants (as suggested in the Spens report) could and should be met in other ways, such as an adequate capitation fee. The scheme will be reviewed in the light of experience within a year of its inception.

Miscarriages and Obstetric Emergencies

182. The Ministry has now agreed that treatment for a miscarriage is outside the range of a general practitioner's term of service, and that a doctor may claim a Part I fee for attending a miscarriage after the eighth week of the commencement of pregnancy.

As in the case of miscarriages, the Ministry has agreed that emergency confinements will qualify for Part II payments provided the patient is not booked with any other doctor and the doctor is not called in by a Local Health Authority midwife.

Medicines and Appliances for Doctors' Surgeries

183. The Ministry is investigating the possibility of allowing a doctor to order on an official prescription form stocks of medicines for use in surgeries. Details of the arrangements in force in Scotland have been sent to the Ministry.

Specialization of General Practitioners

184. Discussions are continuing with the Ministry in furtherance of the policy that some degree of specialization in general practice should be encouraged.

Frivolous or Unjustified Emergency Calls

185. Representations have been made in favour of the reintroduction of rules for the conduct of patients, with disciplinary machinery to be applied in the event of non-observance. The revision of the medical card has been suggested as a first step.

Treatment of H.M. Forces on Leave

186. The War Office has been informed that its proposal to treat as temporary residents members of the Forces who are obliged to seek treatment by civilian doctors whilst on leave is not acceptable.

CONSULTANTS AND SPECIALISTS

Proposed Terms and Conditions of Service of Hospital Medical Staff

(Continuation of para. 60 of Annual Report)

187. The Central Committee has received no fewer than 400 comments and recommendations from Regional Consultants Committees and Special Groups of the Association upon the proposed terms and conditions of service issued by the Ministry and published in the *Supplement* of March 19. Many of the comments and suggested amendments were in similar terms and revealed a considerable measure of agreement throughout the country. The committee, having examined the recommendations in detail, has submitted to the Joint Committee a statement of the points upon which it desires representations to be made to the Ministry.

The Joint Committee, after considering the views of the Central Committee together with those of its other constituent bodies, will enter into immediate negotiations with the Ministry, and it is hoped that the Ministry's reply will be available for publication early in June. Pending the outcome of these negotiations and the final approval of the terms of service by the profession, individual consultants and specialists have been advised not to accept permanent contracts if invited to do so.

Security of Tenure

(Continuation of para. 61 of Annual Report)

188. The Ministry proposes that no fixed period of tenure shall be specified in the contract of service of a specialist, but that where he felt his appointment was being unfairly terminated he should be entitled to send a statement of the facts to the Minister, who would obtain the views of the Board and seek the advice of a professional committee consisting of representatives of the Ministry and of the profession under the chairmanship of the Chief Medical Officer.

The committee has reaffirmed its view that there should be security of tenure until retiring age, except for professional misconduct or incapacity, and has asked the Joint Committee to make further representations to the Ministry to this effect.

A problem associated with security of tenure is the avoidance of appreciable variations in the amount of work rendered by specialists in contract for part-time services. The committee is recommending that where for any reason, such as a change of hospital user, the number of sessions performed by a specialist at any one hospital is curtailed, the responsibility of finding alternative sessions shall be with the Regional Board, or alternatively with the Ministry. The Minister has reminded the Boards of his moral obligation to ensure that specialists displaced as a result of hospital reorganization are given alternative duties.

Betterment

189. The proposed basic salary scale for specialists represents a betterment of approximately 20% on the scale recommended by the Spens Committee, with no betterment added to the special distinction awards. This the committee considers grossly inadequate, and it is wholeheartedly supported by the

Regional Committees in continuing to press for a betterment factor consistent with the rise in the cost of living since 1939. Failing agreement by the Ministry for an increased betterment factor the committee proposes that the issue shall be raised through the Whitley Council machinery at the appropriate time. The committee is also urging that the betterment should be applied to the merit awards as intended by the Spens Committee.

Selection of Specialists

Senior Hospital Medical Officers

(Continuation of para. 62 of Annual Report)

190. The Ministry's proposals include a senior hospital medical officer grade (£1,300-£1,750) for senior officers performing general clinical duties but who are not of specialist status and who are not trainees.

The committee feels that the creation of this grade, necessary as it may be for the appropriate classification of certain transferred officers, is fraught with danger in that it might lead to the establishment of two grades of specialist, involving a process of dilution which would be most undesirable.

It is therefore insisted that the grade shall not be applied to practitioners of specialist status, and has recommended to the Joint Committee that the grade should be used only as a temporary expedient, and that no future appointments should be made in this grade. For the time being advertisements for appointments involving specialist duties in this grade will not be accepted for the *Journal*. The committee has also proposed that machinery should be set up whereby the status of practitioners graded as senior hospital medical officers may be reviewed from time to time, with a view to their up-grading to the rank of specialist in appropriate cases.

The assessment of status of members of hospital medical staffs undertaken by professional review committees is nearing completion, and in some regions practitioners, hitherto practising as specialists and holding interim contracts as such, have already been informed by their boards that they are to be placed in the senior hospital medical officer grade.

The committee is strongly of the opinion that there has been an absence of uniformity as between the regions in assessing the status of hospital staff. It believes also that the grade of senior hospital medical officer has not been clearly defined, and that review committees have regarded it as a junior or associate specialist grade.

At the moment there is no right of appeal from the arbitrary decision of a review committee, except to that body. The Ministry has been strongly urged to establish an independent appeal machinery in the form of a central professional committee, or alternatively three or four area committees to investigate the claims to specialist status of practitioners who are aggrieved at the decision of a review committee.

Pay-beds

(Continuation of para. 59 of Annual Report)

191. A number of cases have been reported where patients, having agreed to receive hospital treatment privately, have subsequently appealed to the board to be relieved from the necessity of paying the specialist's fee and to be regarded as public patients. In some instances the specialist has been handicapped in pressing his fee by the absence of any written undertaking by the patient to pay him professional charges. The committee has drawn up a model form of undertaking which it proposes to make available to the Regions.

PRIVATE PRACTICE

Examination of Candidates for the Women's Land Army

192. After representations from the Council the Ministry of Agriculture and Fisheries has increased the sessional rates for the examination of volunteers to the Women's Land Army from £2 2s. for a session covering five to eight examinations, and a special fee of £2 12s. 6d. where ten cases were examined, to £2 12s. 6d. for a session of six to eight cases, with a further increase of 10s. 6d. for each additional examination after the eighth, up to a maximum of £5 5s. for a session of 14 to 16 examinations.

Independent Referees of the Ministry of Labour*(Continuation of para. 81 of Annual Report)*

193. Following arrangements made by the Ministry of Labour for the payment of a fee of 12s. 6d. in both disputed and undisputed cases where persons are referred for medical examination to determine their fitness for a particular employment, the Council has now accepted a proposal of the Ministry that with effect from April 1, 1949, payment for these examinations where they are undertaken on a sessional basis be increased from £2 2s. to £2 12s. 6d. for a two-hour session involving the examination of five to eight persons.

Forms of Examination for Transport Personnel

194. At the Annual Representative Meeting, 1948, a proposal by South-east Essex Division was referred to the Council, suggesting that forms for the examination of transport personnel, bus drivers and conductors, etc., should be uniform, that the amount of the fee should be clearly stated, and that the company or transport authority should be responsible for payment thereof. The Council has considered a statement from the Ministry of Transport that the forms of report for the medical examination of an applicant for a licence to drive a public service vehicle and an applicant for a licence to act as conductor of a motor omnibus or a motor coach, which were agreed between the Ministry and the Association in 1931, are still in use and that no major amendments to these forms are proposed. The Ministry also stated that it is aware of certain instances where individual transport undertakings are using different forms of report for the re-examination of drivers and conductors. The Ministry added, however, that it would not be possible to consider the standardization of these reports for some considerable time, until the nationalization of public transport undertakings has been completed. The Council has had regard to the fact that the initial medical report is required to support an application to the licensing authority by a private individual and not by a company or transport authority, and that in some instances the applicant may not become an employee of a company or transport authority until he has obtained the required licence. The Council proposes to take no action to press the transport authorities to accept responsibility for the payment of an agreed fee where an application is made for a licence to drive a public service vehicle or to act as a conductor of a motor omnibus or motor coach, or to press for the introduction of standard forms and agreed fees for the re-examination of transport personnel until the nationalization of transport undertakings has been completed.

OCCUPATIONAL HEALTH**A Comprehensive Occupational Health Service**

195. The Council now submits, in Appendix VII, a report on a comprehensive occupational health service. It thinks that an attempt to plan the detailed structure of a comprehensive service would be premature at the present time. Its report therefore contains recommendations of a general character only, the chief of which are (1) that the central authority responsible for the planning and supervision of a national occupational health service should be the Ministry of Health, and (2) that, before the existing occupational health service is expanded, surveys should be arranged by the Ministry of Health to ascertain the needs of different areas. The Council recommends:

Recommendation: That the Report on a Comprehensive Occupational Health Service (Appendix VII) be approved.

The National Dock Labour Board*(Continuation of para. 98 of Annual Report)*

196. Recent discussions with the National Dock Labour Board have removed certain misunderstandings that had arisen as to the work which the Board had authorized its medical officers to carry out at Avonmouth Docks. The Council, while still opposed in principle to work of this kind being performed by public health medical officers in receipt of full-time salaries, is now satisfied that no exception can be taken to the policy of the Board in regard to the scope of the duties undertaken by its medical officers. In these circumstances the Council has

decided that advertisements of medical appointments under the Board will be accepted if offered for publication in the *British Medical Journal*.

NURSING*(Continuation of para. 104 of Annual Report)*

197. The Nurses Bill has now been presented in the House of Lords. Its main object is to improve the training of nurses.

(a) by reconstituting the General Nursing Council, providing for a stronger educational element and for the representation of nurses on a territorial basis;

(b) by setting up Standing Nurse-Training Committees for regional hospital areas with the duties of promoting improvements in the methods of nurse-training and advising and assisting the training institutions and the General Nursing Council in matters connected with such training;

(c) by empowering the General Nursing Council to adopt by resolution approved experimental schemes of training differing from the training prescribed by their Rules;

(d) by providing funds for nurse-training, for expenditure of such descriptions as the Minister may specify, through the General Nursing Council and the Nurse-Training Committees instead of through the administrative budgets of the Regional Hospital Boards and Boards of Governors.

The Bill, which does not extend to Scotland or Northern Ireland, has been described by a Government spokesman as a "finely balanced" document designed to meet, so far as possible, the views expressed by various interested bodies when the draft legislative proposals were under discussion. Although differing in important ways from the draft proposals it does not fully meet the criticisms which were made by the Council.

In the first place the Council thought it inappropriate that the administration of the special funds to be provided for nurse-training should be included among the duties of the reconstituted General Nursing Council. It recommended that a new body, comparable with the University Grants Committee, should be set up to perform this function. This recommendation has not been accepted.

Secondly, the Council, while agreeing that, so far as is practicable, nurse-training should be freed from the limitations that have been imposed on it in the past by the staffing requirements of the hospitals, considers that training cannot be divorced entirely from staffing. It has therefore been anxious that the new regional training committees should be essentially advisory and should not have wide executive powers such as would enable them to impose their requirements on the statutory authorities responsible for the provision of hospital services. The Bill seems to meet the Council's views on this matter by making it the duty of the nurse-training committees to "advise and assist" the Hospital Management Committees and Boards of Governors of teaching hospitals.

Thirdly, the Council, although it welcomes the proposal to provide separate funds for nurse-training, thinks that it is inadvisable to include in the training budget the whole of the expenditure incurred in the payment of training allowances to student nurses. The student nurse is in part an apprentice or employee, and the Council considers that part of her "training allowance" should be received from the hospital authority as salary for services rendered to the hospital. The Hospital Management Committee or Board of Governors is liable for acts of negligence by its student nurses, and unless its status as employer is clearly established it will be unable to exercise the control over the student nurse which its legal responsibility for her actions renders desirable. The intention of the Bill in this matter is not clear, but the Council will endeavour to secure any necessary amendment at the Committee stage in the House of Lords.

The Council will seek also an amendment to ensure that experimental schemes of nurse-training will be instituted only in agreement with the Hospital Management Committees or Boards of Governors concerned, and certain amendments of the First and Second Schedules to the Bill, which set out the proposed constitution of the General Nursing Council and the nurse-training committees. Its objects here are to ensure that certain classes of persons—and, in particular, medical practitioners—will be represented on these bodies and that the General Nursing Council will have the power (granted by the Bill to the nurse-training committees) of appointing its own chairman.

PUBLIC HEALTH

Salaries in the Public Health Service

(Continuation of para. 105 of Annual Report)

198. Certain local authorities have requested their medical officers who are due to retire in the near future to remain in office for the time being. This action may have been taken as a result of the policy of the Association, which includes the refusal by the medical press to publish advertisements of appointments in the public health field which do not comply with the Association's recommended new scales.

The Council has given consideration to this matter and has decided to take no exception to arrangements made prior to Feb. 28, 1949, for a medical officer to remain in office after the date on which he is due to retire, provided the salary conforms to the modification of the Interim Revision of the Askwith Agreement. Similarly, the Council would take no exception to arrangements made after Feb. 28, 1949, provided the medical officer is remunerated at the appropriate step in the new scales recommended by the Association. No other arrangement is, however, regarded as acceptable.

Fees Payable by Local Authorities for Part-time Work

(Continuation of para. 106 of Annual Report)

199. Negotiations on fees for part-time work undertaken by medical practitioners for local authorities will take place on May 31.

Midwives Acts—Fees for Attendances and Post-natal Examinations

(Continuation of para. 108 of Annual Report)

200. The National Health Service (Amendment) Bill makes provision in Clause 20 (2) for the extension to three months of the period during which claims may be submitted by practitioners called in to assist a midwife. The Council is pleased to note that the Ministry has acted upon its representations in this matter.

Joint Committee on Equal Pay

201. The Association is represented on the Joint Committee on Equal Pay established in 1946 to consider the question of equal pay in all its aspects. In addition to the Association, the following bodies are also represented on the Joint Committee: Medical Women's Federation, Civil Service National Whitley Council (Staff Side), Educational Institute of Scotland, National Association of Local Government Officers, National Federation of Professional Workers, and National Union of Teachers.

Information has been received that the Joint Committee is considering an approach to the Government and to the political parties on the policy of equal pay in the professional field, and the Council has decided to give its full support to the Joint Committee on the understanding that any approach should be to all political parties and should be strictly non-political in character.

The Council is also recommending the inclusion in the Joint Committee of representatives of the nursing profession, medical auxiliaries, and certain important teaching organizations.

Lunacy Act

202. The Ministry was recently approached on the question of the responsibility of local health authorities for the payment of fees to medical practitioners carrying out examinations or issuing certificates or recommendations under the Lunacy, Mental Deficiency, and Mental Treatment Acts. The Council is glad to note that provision has been made in Clause 17 of the National Health Service (Amendment) Bill for the payment of such fees by local health authorities.

Local Government (Compensation) (Amendment) Regulations

203. Amending regulations have been made to enable a period of war service or national service to count in the eight-year period necessary to qualify for compensation on loss of employment or diminution of emoluments under the Local Government (Compensation) Regulations, 1948. This omission from the original regulations was brought to the attention of the Ministry by the Association.

"BRITISH MEDICAL JOURNAL"

Popular Health Journal

204. The proposal to publish a popular health journal was put forward by the Science Committee in January, 1948, and referred to the Journal Committee for its consideration. The Journal Committee later reported to the Council that it had under sympathetic consideration the possibility of publishing such a journal under the general editorship of the Editor, *British Medical Journal*. A preliminary memorandum on the subject, reviewing existing health journals and giving some preliminary estimates, was put before the Journal Committee in October, 1948. A subcommittee was then appointed to go into financial and other details. This subcommittee consisted of the Chairman of Council, the Treasurer, the Chairman of the Journal Committee, the Chairman of the Publishing Subcommittee, and the Chairman of the Science Committee. The subcommittee, after taking expert advice, finally recommended to the Journal Committee the publication of a popular health journal. The Journal Committee carefully examined the proposals put forward by the subcommittee, and endorsed its recommendation.

At its meeting on May 11, 1949, the Council was presented with a full account of the proposals and a detailed provisional estimate of income and expenditure. It also had before it a "dummy" of the proposed journal. The Council approved the Journal Committee's recommendation and accepted also a related recommendation from the Finance Committee. The Finance Committee had raised no objection on financial grounds "on the understanding that the date for the inception of the new journal is determined by the Council at the meeting in March, 1950, in the light of the financial position then obtaining."

Recommendation: That the Association undertake the publication of a popular health journal, and that the date for the inception of the new journal be determined by the Council in March, 1950, in the light of the financial position of the Association then obtaining.

ORGANIZATION

Agenda of Representative Meetings

(Continuation of para. 128 of Annual Report)

205. Criticism of the conduct of business at Representative Meetings and particularly Special Representative Meetings has been received from a number of sources. It has been suggested that on several occasions the Agenda has been so long and some items so controversial that it has been impossible for many motions or amendments submitted by Divisions to receive adequate discussion. This situation has led to a feeling of frustration and to demands for review of the machinery for dealing with the Agenda.

The Representative Body appointed a small Committee to consider this problem. A report was submitted by this Committee to the A.R.M. 1946, when it was decided that no action should be taken to modify the functions of the Agenda Committee, but to vary the constitution of that Committee by the addition of two members elected by the Representative Body. The A.R.M. 1948 decided that the number of members elected by the Representative Body to the Agenda Committee should be increased from two to four.

The Constitution and Functions of the Agenda Committee

It is important that the position of the Agenda Committee should be clearly understood. The Committee consists, under the Standing Orders of the Representative Body, of the Chairman and Deputy-Chairman of the Representative Body, the Chairman of Council, and four members appointed by the Representative Body. The Committee has power to co-opt from among the Chairmen of Standing Committees not more than four additional members having regard to the nature of the business to be transacted.

The Standing Orders of the Representative Body explicitly provide that the function of the Agenda Committee is to arrange the Agenda so that motions by Divisions and Branches shall be strictly relevant to paragraphs of reports submitted by the Council; and the Committee is empowered to place other motions not strictly relevant to the Council's report in an

appropriate order on the Agenda. In the case of Special Representative Meetings the instruction to the Agenda Committee is to report as to the method of dealing with the Agenda of the Meeting. In short, the sole function of the Agenda Committee is to arrange the order of business. The Committee submits a formal recommendation of its proposals to the Representative Body, but it is always open to that body to vary the order of business.

It will be clear, therefore, that the Agenda Committee has no power of veto. It cannot exclude a motion on the ground that it is already covered by another, it cannot combine motions which are similar in intent and differ only in wording, nor has it authority to frame a composite motion covering a number of motions from Divisions in the same field. As matters stand every Division of the Association has an absolute right to have its motion included in the Agenda, provided the motion is submitted within the prescribed period laid down in Standing Orders.

The Business of Annual and Special Representative Meetings

Experience has shown that there is no special difficulty in dealing with the business at the Annual Representative Meeting, which extends over 3½ days; but that the problem of congestion of the Agenda is more likely to arise at Special Representative Meetings. In the case of the Annual Representative Meeting the business centres upon the Annual Report of the Council; in the ordinary course of events there is ample time for Divisions to consider that report and to submit motions for inclusion in the Agenda and for the meeting to deal with all the items on the Agenda. Special Representative Meetings, however, are invariably called at short notice to deal with special problems, some of which are of an urgent nature. It is not unusual for a very large number of motions to be put forward at such meetings by Divisions and Branches, and it is this situation which has given rise to proposals for modifying the present procedure so as to simplify the consideration of the questions which the meeting has been called to discuss.

In recent years the Agenda Committee has endeavoured to meet the problem by "starring" particular motions which, in its view, covered a number of motions on the same subject and on which the main discussion should take place. It has been left to the Chairman of Representative Body to determine which motions were covered by the starred motion or other motions and to rule that the representatives of constituencies submitting motions held to be covered should speak to the selected motion. This has led to a position where, in speaking upon the selected motion, a number of representatives have covered the same ground. There has thus been repetition and a badly balanced debate. "Starring" has also been found unsatisfactory, as the representatives of some constituencies have felt that the "starred" motion on which the discussion took place did not bring out the precise point made by their constituency.

It will, however, be agreed that an Agenda containing several hundred motions is unwieldy, that it adds considerably to the burden of chairmanship, and is conducive to an atmosphere of pressure and a feeling of working against time.

A further problem arises when constituencies submit long motions covering a number of subjects. Such motions are not conducive to the expeditious conduct of Representative Meetings, and it is ordinarily to the advantage of constituencies to frame their motions as precisely as possible.

Possible Methods for dealing with the Problem of the Congested Agenda

Two methods have been suggested for dealing with the problem of the congested Agenda at Representative Meetings—one local, the other central.

The first would make use of the large local groupings of the Association as a filter between the Divisions and the Agenda Committee. Divisions would be required to refer their motions in the first instance to, say, Branch Councils or to a body composed of Representatives of grouped Branch Councils selected for the purpose—e.g., using the groups for election to the Council. The special body might have power to exclude redundant propositions, to combine similar motions, or itself to frame a composite motion embodying the points contained in the motions submitted by its constituent Divisions and Branches. The method at first sight has an attractive appear-

ance of tidiness and, since it would operate through elected regional bodies of the Association, suggests a proper democratic responsibility. In practice, however, it would probably be rather cumbersome and would require considerable time for function. The Council is convinced that this proposal is unsound. The Divisions are rightly jealous of their autonomy, and any interference with the direct access of a constituency to the Representative Meeting would lead to resentment and delay.

The second method would give to the Agenda Committee similar powers and is open to the same objections. Even if the power were conceded and the Agenda Committee were to recommend to the Representative Body in its report that certain motions should be altered or eliminated, this might lead to so much discussion by representatives of affected constituencies that it would be better to discuss the actual motion. The Council believes that it would be undesirable and possibly dangerous to place in the hands of the Agenda Committee the power to exclude or to alter motions submitted for the Agenda.

The following is a possible method of dealing with the problem:

(i) To broaden the basis of the Agenda Committee.

(ii) To give the Agenda Committee power to compose an additional motion covering a number on the same subject, or where this is unnecessary to decide (by starring) the particular motion in a group on which discussion should take place, it being understood that the right of a Division to include a motion in the Agenda of Representative Meetings is retained;

(iii) To give suitable opportunity for representatives whose motions have been grouped, or held covered, to choose from among their number a proposer who would move the motion and be allowed to speak for ten minutes. Other speakers would be limited to five minutes;

(iv) The report of the Agenda Committee would not be subject to the approval of the meeting;

(v) Divisions and Branches should be encouraged to seek the advice of the Regional Secretaries at Head Office in the framing of resolutions for the Agenda of Representative Meetings.

The Council in submitting this report is anxious that this complex problem should be fully understood in the Divisions and Branches. The essence of the problem appears to avoid restricting in any way the right of a Division or Branch to submit a motion for inclusion in the Agenda, but to give the Agenda Committee such modified powers as will secure that the business of the Meeting is dealt with expeditiously and that there is reasonable time for the consideration of the views of the local units of the Association.

The Council makes no recommendation, as it feels that it would be more appropriate for Divisions to submit motions to the A.R.M. for dealing with the problem when full consideration has been given to the various aspects of the question dealt with in this report.

Procedure followed by Other Bodies

206. Members may wish to know the procedure followed by other organizations in dealing with this problem.

National Union of Teachers.—Some 600 local bodies with a conference of over 2,000 members. Prior to the conference the local bodies are informed of the motions and amendments before the conference and are invited to vote so as to determine the order in which subjects are to be dealt with. The agenda is arranged in the order thus determined, subject to the right of the executive to bring forward matters of urgency. The Agenda Committee must admit motions, etc., of local bodies to the agenda; it has no power of veto, but in the case of motions covering much the same ground it invites the local bodies to elect a select committee to select the motion on which the discussion should take place, and this procedure is usually followed.

The National Association of Local Government Officers.—Some 1,000 local units with a conference of not more than 1,200 members. The Agenda Committee has no power of veto, but it may, without consulting the local units, group and then under one motion or amendment, motions or amendments which have a similar object.

Labour Party.—800 local units; conference of 1,000. Each unit may submit only one motion for the agenda of the conference and one amendment to the preliminary agenda. The proviso that where a question has been decided by the

by the Annual Conference—no motion or amendment concerning such principle may be included in the agenda from a local unit within a period of three years unless with the approval of the national executive.

Arrangements are made for consultations of local units prior to the conference with a view to simplifying resolutions and amendments covering the same subject; there is similarly prior consultation by correspondence on resolutions of local units. The results of such consultation must be forwarded to the head office, failing which resolutions, motions, or amendments will be deleted from the conference agenda.

The Conference Arrangements Committee allocates a timetable for the discussion of subjects and indicates the motions, amendments, etc. (which are not necessarily all those on the agenda paper on the subject in question), to be discussed within the time allowed.

Grouping for Direct Election of 37 Members of Council (Continuation of para. 124 of Annual Report)

207. The Council has given further consideration to the plan for the grouping of Branches and Divisions for the direct election of 37 members of Council.

The Council recommends:

Recommendation: That the following plan for the grouping of Branches and Divisions for election of 37 members of Council be approved:

Group	Area in terms of B.M.A. Branches or Divisions	Proposed No. of seats	Membership
(i) England and Wales			
A	Divisions of North of England Branch in North Eastern Region (it being left to the discretion of the Branch to suggest a division of the Group into 2 electoral areas)	2	1,764
	Cumberland		
	Westmorland (part)		
B	East Yorkshire Branch	2	2,767
	Yorkshire Branch		
C	Lancashire and Cheshire and Isle of Man Branches (it being left to the discretion of the Branches to suggest any appropriate electoral divisions for the area)	4	4,305
D	Lincolnshire Branch	2	1,599
	Derbyshire Branch		
	Nottinghamshire Branch		
	Leicestershire Branch		
E	Birmingham Branch	2	2,473
	Staffordshire Branch		
	Worcester and Hereford Branch		
F	Berks, Bucks, and Oxford Branch	1	1,309
	Northamptonshire Branch		
G	Cambs and Hunts Branch	1	995
	Norfolk Branch		
	Suffolk Branch		
H	Metropolitan Counties Branch (Divisions in Middlesex) (it being left to the Metropolitan Counties Branch to suggest any appropriate electoral division of the area)	2	1,913
I	Metropolitan Counties Branch (Divisions in London, Stratford, and S.W. Essex) (it being left to the Metropolitan Counties Branch to suggest any appropriate electoral division of the area)	4	5,273
	Hertfordshire Branch	1	1,393
	Essex Branch		
	Bedfordshire Branch		
	Surrey Branch	2	1,838
	Kent Branch	1	1,271
	Sussex Branch	1	1,062
	Southern Branch	1	1,394
	Dorset and West Hants Branch		
	Bath, Bristol and Somerset Branch	2	1,618
	Gloucestershire Branch		
	Wiltshire Branch		
	South Western Branch	1	999

Group	Area in terms of B.M.A. Branches or Divisions	Proposed No. of seats	Membership
Q	North Wales Branch	1	699
	Shropshire and Mid-Wales Branch		
R	South Wales and Monmouthshire Branch	1	1,293
(ii) Scotland			
S	Aberdeen Branch	1	1,333
	Dundee Branch		
	Northern Counties of Scotland Branch		
	Perth Branch		
T	Edinburgh and South-East of Scotland Branch	1	1,544

SCIENCE

Association Prizes

(Continuation of paras. 139–142 of Annual Report)

208. The Council thanks the following, who have assisted in judging the awards for the Association Prizes made in 1949: Dr. Janet Aitken, Dr. G. O. Barber, Professor F. J. Browne, Professor Sir Henry Cohen, Miss M. H. Cordiner, Mr. Ernest Finch, Dr. R. G. Gordon, Sir Gordon Gordon-Taylor, Professor C. W. Illingworth, Mr. R. Kennon, Dr. J. C. Matthews, Miss E. J. Merry, Dr. C. E. Newman, Mr. F. A. Williamson, Noble, Sir Leonard Parsons, Miss Agnes Pavey, Professor Arnold Sorsby, Mr. R. W. D. Turner, Professor R. J. Willan, and Professor James Young.

The Council also thanks those who have visited and reported on the Association's Research Scholars—namely, Professor J. H. Burn, Professor Sir Henry Cohen, Brigadier D. B. McGregor, Professor T. J. Mackie, Professor E. D. Telford, and Professor R. Milnes Walker.

Foreign Corresponding Members

209. In the list of Foreign Corresponding Members contained in para. 144 of the Annual Report of Council Professor Adolf Meyer is described as Professor of Psychiatry, Phipps Institute, Baltimore. This is incorrect. Professor Meyer is Professor Emeritus of Psychiatry in the Johns Hopkins University School of Medicine, Baltimore.

ARMED FORCES

National Service Officers

210. The Council has been informed that the new rates of marriage allowance for members of the Armed Forces which came into operation on Nov. 24, 1948, and were granted to meet the increased cost of living, do not apply to those called up under the National Service Acts since Jan. 1, 1947. Discrimination also exists in the matter of annual leave: the Council's view is that the amount of leave granted should be comparable to that which the officer would receive in civilian life.

The Council has informed the Ministry of Defence and Service Departments that it deplors this discrimination, which reacts particularly harshly upon medical officers, many of whom, owing to the relatively late age at which they are called up for National Service, are married before entry into the Forces.

Pensions

(Continuation of para. 151 of Annual Report)

211. The Council has now received from an actuary a report comparing retirement benefits in the Armed Forces with those

in the National Health Service. In view of his conclusion that they compare satisfactorily the Council has decided to take no further action at the moment. The matter will be reopened, however, if current negotiations lead to any marked increase in the remuneration of National Health Service practitioners.

SCOTLAND

Representation of Scotland on the Council of the Association (Continuation of para. 124 of Annual Report)

212. The proposals for modification of the constitution of the Council of the Association as they affect the direct representation of Scotland on that body have been considered by the Scottish Committee and accepted.

Organization of Consultants and Specialists in Scotland (Continuation of para. 153 of Annual Report)

213. The Central Consultants and Specialists Committee (Scotland) has considered in their relation to Scotland the proposed terms and conditions of service of hospital, medical, and dental staffs, and has referred its comments to the Central Consultants and Specialists Committee. It has appointed an Ophthalmic Services Subcommittee to replace the former Ophthalmic Services Subcommittee of the Scottish Negotiating Committee; and has prepared, by means of a special subcommittee, a report on the remuneration and status of medical superintendents and the policy which should govern their appointment in the future. The question of a Joint Subcommittee with the General Medical Services Subcommittee (Scotland) to deal with the problem of general practitioners in Scottish hospitals and institutions is under consideration.

Organization in Respect of General Medical Services under National Health Service in Scotland (Continuation of para. 154 of Annual Report)

214. The General Medical Services Subcommittee (Scotland) is discussing with representatives of Scottish Local Authority Associations the circumstances under which fees should be payable to general medical practitioners for services rendered to local authorities and the question of what services are covered by the fees payable to such practitioners under the Health Service. A number of other matters connected with the general medical service in Scotland have been discussed with the Department of Health—e.g., expenses of local medical committees, the method of application to and scope of the Inducement Fund in Scotland, telephone charges in rural practice, and the remuneration of general practitioners giving emergency dental treatment in the Highlands and Islands areas. The question of the direct access of general practitioners to x-ray facilities without prior reference to physicians and surgeons at out-patient departments of hospitals is under consideration, and is also under discussion by the appropriate Advisory Committee of the Scottish Health Services Council.

Health Centres and Group Practice (Continuation of para. 155 of Annual Report)

215. Resulting from the discussions with the Secretary of State, local medical committees in Scotland have been asked for suggestions with a view to easing practice difficulties pending the development of health centres, in order that the matter may be further discussed with the Department of Health. The question has also been referred to the Scottish Health Services Council and is under consideration by one of the Standing Advisory Committees of the Council.

Scottish House

216. Plans are under consideration for alterations to the Scottish House at Nos. 6 and 7, Drumsheugh Gardens, Edinburgh, to provide common-room, reading-room, and writing-room accommodation for members, which at present is not available, adequate cloak-room and storage accommodation, catering facilities, and increased accommodation for the staff.

HEALTH CENTRES

(Continuation of para. 3 of Annual Report)

217. When the Council issued its Interim Report on Health Centres in July, 1948, certain matters remained to be considered. These have since been dealt with and the Council has approved the paragraphs below for inclusion in its final report, copies of which will be available at the A.R.M. The association of general practitioners with hospitals is a subject which is to receive separate attention and is now excluded from the report.

Health Centres and Health Education

In the Council's Interim Report a brief reference was made to health education as an item in the minimum range of service that health centres should provide. Further consideration has since been given, and the Council's view is that it is essential to preserve the personal and private nature of medical attention which is such a valuable feature of existing family medical practice. It believes that this is also the view of the general public. While realizing that family practice as it exists to-day is incomplete when separated from the work of the local authority clinics, and urging their reunion, the Council wishes to find in the resulting health centre none of the impersonal, institutional atmosphere of the clinic or hospital out-patient department. At first sight the health centre offers opportunity for all methods of health propaganda, but many of them are incompatible with this ideal.

The Council is therefore definitely opposed to the use of posters, exhibitions, gramophone records, and films in health centres. It regards the individual education continually carried on in the family doctor's everyday work as probably the most effective kind; under the conditions of close co-operation envisaged by the Council its influence would be extended by the work of the health visitors attached to the health centre. Leaflets, in the hands of both doctors and nurses, would be of value, especially if compiled by those who used them. Group instruction and discussion might be useful and compatible with the Council's ideals if the groups were small, confined to the patients of the centre, and concerned with specific subjects such as infant care, minor ailments, and first aid; their success would no doubt vary with the personality and ability of the doctor conducting them. In considering the question of public lectures it should be remembered that general practitioners as a class are not experienced at handling audiences, nor likely to find the time to become so. Also the Council feels that public lecturing at a health centre by the staff might transgress the ethical principles accepted by the profession. This would not apply to lectures by the medical officer of health or other visitors; but the Council believed that advertised public lectures on health topics are seldom well attended, with the sole exception of those on venereal disease.

The Council is of opinion that, excepting the intimate methods of personal instruction, health education should be conducted not from health centres but from educational centres. It does indeed already start in the schools; should it not continue to be associated with other subjects of education for all ages, through such agencies as the technical colleges, the W.E.A., the cinema, and the radio? It seems likely that in this way a larger proportion of the public would be reached and a more balanced knowledge of the place of hygiene in human life would be imparted. After all, most people will not go near a health centre unless they have some specific medical need, and it is probably not desirable that they should.

To sum up, the Council has come to the conclusion that the private health education inseparable from personal medical attention is more important and is the only kind appropriate to a health centre. Any attempt to use the centre for public health propaganda should be actively discouraged in the experimental period, lest the public be given quite a wrong impression of the type of health centre the Council hopes to see evolved.

Section 21 of the National Health Service Act, 1946, places upon local health authorities the duty of providing health centres at which facilities shall be available for all or any of a number of purposes, including the publication of information on questions relating to health or disease, and for the delivery

of lectures and the display of pictures or cinematograph films in which such questions are dealt with. The wording of this section, however, leaves the Council in no doubt that its provisions are permissive and not compulsory so far as they relate to health education in health centres.

Health Centres in Rural Areas

The scattered nature of medical practice and the limited means of transport available to the lay public in country districts materially affect the advisability of the establishment of rural health centres. Patients would be unlikely to attend a health centre situated in a less convenient place than the residence of the nearest practitioner. The problem therefore resolves itself into one of geography, and it is recognized that different localities must vary in regard to the above factors. Furthermore, health centres of the communal surgery type are unsuitable in village communities. For these reasons it is impossible to lay down any hard-and-fast rules for the establishment of health centres in rural areas.

One of the disadvantages of rural practice is the difficulty in obtaining specialist opinion. The Council is inclined to the view that in rural areas a cottage hospital at which a consultant service is available might well be combined with a health centre and thus serve a dual purpose.

The Council is interested in the experiment of the Joseph Rowntree Village Trust, which is providing a mobile unit to visit outlying districts. It is to be used primarily for maternity and child-welfare clinics and is staffed by a nurse and orderlies and is available for the doctors of the locality. The Council feels that this experiment should be watched with interest and, if successful, copied in suitable localities, perhaps with extended functions.

Specialist Services

When a general-practitioner specialist is a member of a health centre staff his special qualifications will increase the range of service provided for the patients, and his colleagues in the centre will refer cases to him for consultation and treatment.

The Council considers, however, that no advantage would be gained by specialists who work exclusively as such holding sessions at health centres. Except for visits to patients confined to their homes, it will be much more efficient for their work to be concentrated at the hospital, which contains all the equipment and the auxiliary services they require. There should, however, be organized co-ordination between the health centre and the local hospitals. When consultation, investigation, or specialist treatment at the hospital is required the health centre patient will be referred to the hospital out-patient department, or if necessary his family doctor will call out the specialist to see him in his home. The health centre may occasionally form a convenient meeting-place for the three.

Radiology is an example of a specialty which should in the Council's opinion usually be conducted by a specialist devoting to it the whole of his time. The field of his work is so great, and adequate equipment to cover the field so expensive, that the hospital is his sole appropriate place. The Council is, therefore, opposed to the provision of any x-ray apparatus at health centres, except possibly in the isolated rural areas. It should be possible for a health centre doctor to refer a patient direct to the radiologist as to any other hospital specialist.

In the same way the pathologists and their elaborate equipment must be situated in the hospital. The Council considered various ways of improving the very inadequate pathological services now available to the general practitioner. It came to the conclusion that only simple tests usually carried out by nurses and doctors should be done on the health centre premises. Various forms of ramification of the hospital laboratory to the periphery were considered, and rejected in favour of the frequent and rapid transport of specimens to the laboratory and telephoning of reports. This would be cheaper than any other method as well as more efficient, even if done on an elaborate scale involving, for instance, the employment of a motor-cycle messenger by the laboratory. Whenever it is desirable the patient himself should be sent direct to the clinical pathologist, or the clinical pathologist called to his house.

OVERSEAS

Private Practice by Colonial Medical Officers

218. The Council has considered the report of the Commission on the Private Practice of Medicine and Surgery by Officers of the Department of Medical Services, Nigeria (by Sir Sidney Phillipson), and has noted with satisfaction that the Commission's conclusions on this difficult subject are broadly the same as its own—namely, that private practice by Colonial medical officers should be forbidden where private practitioners of good standing are available, but that where this alternative does not exist and Colonial medical officers are obliged to attend private persons, they should be authorized to charge and retain fees for so doing.

INTERNATIONAL RELATIONS

219. The Association has continued to send distinguished British practitioners to lecture abroad. The following list shows the lecturers and countries visited since June, 1948, and the subjects of the lectures:

Lecturer	Country	Subject
R. G. Pulvertaft, F.R.C.S.	Portugal	Orthopaedic Surgery
I. Lawson Dick, F.R.C.S.	Norway	Orthopaedic Surgery
Professor G. Jefferson, F.R.C.S.	Austria	Neurology
Dr. J. S. Heller	Austria	Pharmacology
Professor M. J. Stewart	Czechoslovakia	Pathology

Mr. St. J. D. Buxton, F.R.C.S., has been sent to Greece to lecture on orthopaedic surgery, accompanied by a limb-fitting technician, whose visit was arranged by the British Council. Reports received by the Association indicate that these lectures and visits continue to be highly appreciated.

Receptions were given at B.M.A. House to the International Congress of Industrial Health in September, 1948, and the International Congress of Mental Health in August, 1948.

MEDICAL BENEVOLENCE

220. The sum of £8,972 10s. 4d. was received during 1948 by the Charities Trust Fund of the Association for medical charities, and the following statement shows the amounts collected and distributed during the twelve months:

	1948	
	£ s. d.	
Amounts received from:		
(a) Royal Medical Benevolence Fund—		
(1) Allocated from B.M.A. Charities Trust Fund for General Fund	4,455 19 2	
(2) Earmarked for Fund	3,573 8 8	
(b) Royal Medical Foundation of Epsom College:		
(1) Allocated from B.M.A. Charities Trust Fund for General Fund	280 3 0	
(2) Earmarked for General Fund	62 19 6	
(c) Royal Medical Benevolence Fund:		
(1) Allocated from B.M.A. Charities Trust Fund for General Fund	1,950 0 10	
(2) Allocated from B.M.A. Charities Trust Fund for Sherman Biggs Fund	216 13 4	
(3) Earmarked for General Fund	856 16 0	
(4) Earmarked for Sherman Biggs Fund	23 7 0	
(d) Sir Charles Hastings Fund	3,045 17 2	
(e) Society of Ireland—		
Earmarked for Fund	62 19 6	
(f) Sir Charles Hastings Fund	122 10 9	
	£8,972 10 4	

The amounts received through the Fund are gratifying and show that the interest in the medical charities is being maintained. The medical charities are constantly receiving demands on their funds, and the Council hopes that members of the profession will do all they can to help.

H. GUY DAIN,
Chairman.

APPENDIX VII

A COMPREHENSIVE OCCUPATIONAL HEALTH SERVICE

Introduction

1. It is the considered opinion of competent authorities, both medical and lay, that there should be an expansion of occupational health services. This is the opinion of important groups such as the Trades Union Congress, the Royal College of Physicians of London, the Association of Industrial Medical Officers, and the Association of Certifying Factory Surgeons. That it is also the general policy of the Government is shown by statements made by Ministers of the Crown at the International Congress on Industrial Medicine held in London in September, 1948. For example, the Minister of Labour and National Service, according to a report in the *British Medical Journal* of Sept. 18, stated that he strongly supported the formation of a national industrial medical service, and that this was part of the Government's policy.

2. No detailed plan of how any expansion could take place has as yet been published. It is known, however, that the Factory Department of the Ministry of Labour is collecting information on the present medical situation in factories, and that a series of questions relating to the future development of factory medical services was sent to employers by the Industrial Health Advisory Committee of the Factory Department.

3. For various reasons the contributions of the Factory Department to the promotion of health in industry are necessarily limited. The Factories Acts of 1937 and 1948 lay down minimum rather than optimum standards; there are many working communities which are not within their scope; and there are only about 350 inspectors available for visiting the 280,000 work-places covered by the Acts. Moreover, owing to the nature of its relationship with industry, the Factory Department, through its visiting inspectors and Appointed Factory Doctors, can make only a very limited contribution to the solution of the psychological problems of individual and group character which recent experience has shown to be important in the industrial world. In short, advice, inspection, and statutory medical examination, although important, form only part of an occupational health service.

4. In view of the limited scope of the Factory Department, nationalized industries and certain private industries, Government Departments, and public bodies responsible for the health, safety, and welfare of their employees have established their own medical services, realizing that a medical service for the group is necessary for promoting health at work. The 800 part-time and 165 whole-time medical officers in factories are now a vital part of the existing occupational health service.

General Principles

5. It is the view of the Council that there are certain general principles which are basic to any plan for expansion of occupational health services. These principles should form a guide to those persons on whom the responsibility may fall for planning, initiating, or supervising such services.

6. In the first place, the term "occupational health," and its scope, needs definition. Occupational health is concerned with the study of individuals in relation to the physical and psychological demands of their occupations, and of work and the work environment in relation to their effects on health. Occupational health now includes the subjects of industrial or occupational medicine, industrial surgery, industrial physiology, toxicology in relation to industrial hazards, industrial rehabilitation and resettlement, industrial or occupational psychology, and industrial hygiene and engineering. It must be clearly understood that non-medical experts, in collaboration with the doctor, play an active part in the promotion of occupational health.

7. An occupational health service is primarily preventive in character. It is intimately concerned with all human problems in the occupational group. It includes, *o. should include*, (1) a hygiene or environmental service; (2) the assessment of fitness for different forms of employment; (3) a co-ordinated

rehabilitation and resettlement programme; (4) measures for the emergency treatment of injuries and illness occurring at the place of work; and (5) participation in research and educational schemes.

8. Occupational health services should no longer be confined to the practice of medicine in factories. Already schemes operate in coal-mines, in the transport and shipping industries, in public utility companies, for the staff of hotels, restaurants, and shops, for large groups of clerical workers, and for university students. Evidence of the need for development outside the industrial field is contained in the recently published final report of a Committee of Inquiry set up by the Home Secretary and the Secretary of State for Scotland (*Health, Welfare, and Safety in Non-Industrial Employment; and Hours of Employment of Juveniles*, Cmd. 7664).

9. No occupational health service can be successful without the full collaboration of all sections of industry. In any future plans, schemes for the provision of services, and the services themselves, must be acceptable to both managements and employees.

10. Further development and co-ordination by some central authority will be necessary before existing services can become comprehensive, before there can be broad integration of one type of service with another, or before a positive link can be created between occupational health and the National Health Service.

11. In the opinion of the Council, the Ministry of Health is the appropriate central authority to plan and supervise a national occupational health service.

12. This view is taken for the following reasons. First, it is considered a fundamental principle that an occupational health service should be supervised by the Government Department which already has general responsibility for the national health.

13. Secondly, the hospital and specialist services and the general-practitioner service now play an active part in promoting occupational health and will make an even greater contribution in the future. For example, the modern conception of the rehabilitation and resettlement of disabled workers and the need for expert clinical assessment of occupational diseases make an intimate link with the hospital services essential. So far as the general-practitioner service is concerned, a close liaison between the National Health Service and the occupational health service is important because any considerable expansion of the latter service can be effected only by the recruitment of general practitioners adequately trained to undertake work among occupational groups on a part-time basis.

14. Thirdly, the public health service administered by the local health authorities is likely to have increasing responsibilities in relation to occupational health. For instance, health services for small occupational units might be based on health centres provided by local health authorities. These authorities already have responsibility for the health of the school child, and it is generally accepted that a closer link between the school medical service and the health services for juvenile workers is desirable. Further, the public health service, by training and experience, has the preventive approach to health problems which is essential in the sphere of occupational health. Again, the responsibilities of the local authorities in connexion with the location of industry and the provision of residential accommodation and transport services are intimately concerned with the health of industrial workers.

15. Finally, the Council considers that, so far as their contributions to the promotion of occupational health in any future occupational health service of a national character are concerned, the closest possible integration of the three divisions of the National Health Service should be effected.

16. The Council considers it essential that, before there is any expansion of the existing occupational health service, the Ministry of Health should arrange surveys to ascertain the further needs of different areas and the particular character of the service required. Even after such surveys have been conducted, experiments in methods of providing services will be necessary before plans for a comprehensive service can be made. It is for this reason that the Council considers it inadvisable to advance detailed proposals at the present time.

CONFERENCE OF HONORARY SECRETARIES

A Conference of Honorary Secretaries of Divisions and Branches was held at B.M.A. House, London, on May 10 under the chairmanship of Dr. WILLIAM HUNTER (North of England Branch).

The CHAIRMAN OF COUNCIL (Dr. Guy Dain), after welcoming the secretaries, without whose work, he said, the Association would crumble to pieces, reviewed the important events of the past year. He referred with pride to the steadiness of Association membership; the resignations expected in some quarters had not come about, and the membership was now at the peak of 60,441; one thousand members had been recruited during the last three months. On the question of general-practitioner remuneration, it appeared that the Ministry was not yet ready to give an answer. A strong protest had been made against this unreasonable delay. It looked as if the Ministry was endeavouring to put off a settlement for as long as possible. Experience had shown that some modification of the machinery for central bargaining was necessary, and accordingly it had been decided to set up the British Medical Guild. The National Insurance Defence Trust would continue to function; general practitioners who were subscribing through that channel would not, of course, be asked to subscribe to two funds, but means were being created for collecting subscriptions from members in other branches of the profession. The constitution of the Association was being revised, and the proportion of directly elected members of Council would be increased. Dr. Dain also referred to the setting up of the Empire Advisory Bureau and to other services, including the organization, with offices in London, Manchester, and Edinburgh, for putting practitioners in touch with assistants and locumtenents. In view of the great financial strain upon the Association owing to the work connected with the National Health Service, as well as the special services which the Association itself had inaugurated, it was proposed to raise the general subscription by one guinea.

Many questions were asked by the secretaries about the new Service and also about the Guild. The Chairman of Council said he hoped it was understood that all practitioners should be invited, and indeed vigorously persuaded, to allow deductions to be made from their executive council cheques in order that a fund might be created substantial enough to support the profession in case of need. With the increased number of persons now at risk the deduction per person on a doctor's list would enable the fund to increase more speedily than the N.I.D. fund had done.

Questions were also asked with regard to the proposed Association war memorial, which it was suggested should take the shape of an ornamental fountain in the courtyard at Headquarters. A strong feeling was manifest that instead of a memorial in stone it should take the form of educational scholarships for the children of fallen members. The Chairman of Council said it would be open to the Representative Meeting to decide exactly what form the memorial should take.

Regional Offices

The SECRETARY (Dr. Charles Hill) explained the method now in operation for making available in the regions the services of Headquarters secretarial staff. The idea of resident regional secretaries had been canvassed, but it was felt that it would be more useful for the Divisions to have the periodic visits of a secretary who spent two-thirds of his time at Headquarters and thus was able to have and convey a close and detailed knowledge of what was happening at the centre. Offices for clerical purposes in the regions were being started, the idea being to have in each region a place where clerical and general utility services could be provided, and possibly from these beginnings a visiting headquarters for regional secretaries might be created at which they could meet Divisional secretaries and members. Such offices had been established at Oxford, Cambridge, Leeds, Manchester, Sheffield (a tentative arrangement), and Liverpool; negotiations were proceeding in Newcastle, and in Wales an Association House was to be taken, probably at Cardiff. In Northern Ireland a satisfactory arrangement obtained with an office in the Whitla Institute at Belfast.

Dr. W. HUNTER said that the North of England Branch Council feared that this policy of regionalization might overweight the administrative machinery of the Association and require a gradual increase of clerical staff on Civil Service lines. The North of England had had its own office system in operation for many years, and saw no reason for this upheaval. He was very proud of the Divisions and Branches and felt that these were the units that counted—not the administrative regional office. Interference from Headquarters was not desired. "We want not a man from Headquarters to keep an eye on the periphery but a man from the periphery to keep an eye on Headquarters." The regional secretary must not act as a buffer to soften the impact of criticism of central policy from Divisions and Branches. The North of England appealed to Division secretaries to stir up inactive Branches and replace lethargic Branch officials at annual meetings by live men. A Branch could do much to help its Divisions; in practice the Branch was the Divisions and should act as a co-ordinating body.

Dr. R. G. GIBSON (Winchester) urged that members of the secretarial staff should stay a reasonable length of time in the regions, visiting practitioners in their homes if possible. To address a meeting of 10% of the members of the Division was not satisfactory.

In further discussion the value of regional offices for clerical purposes was questioned in some quarters. The secretary of the Gloucestershire Branch said it would be as easy for him to communicate with London as with a regional office situated, say, at Bristol. Dr. Hill, in reply, said he thought it was a fair summary of the discussion that there was approval of the central-cum-local method. He agreed that ideally more time should be spent in the Divisions by the assistant secretaries, but it must be remembered that they were primarily servants of the centre, and that in so far as the periphery sought to influence central policy this must be done through the Representative Body. The visiting secretary was not in a position to accept instructions from a Division on an issue of policy if that policy differed from what had been decided centrally. He also felt that visits to Divisions should continue to be by invitation. No doubt a case could be argued for the creation of more central staff, but this would mean that each member of the staff was only fully aware of a smaller segment of central activity.

The Future Role of Divisions

Dr. J. A. PRIDHAM, chairman of the Organization Committee, drew attention to a memorandum compiled by Dr. L. S. Potter, Assistant Secretary, on the role of the Divisions in the medico-political work of the Association. It was in his view an excellent one. He went on to describe the altered organization which had arisen consequent upon the introduction of the National Health Service, in particular the creation of two autonomous committees—the General Medical Services Committee and the Central Consultants and Specialists Committee. It was important to emphasize that in this new set-up the role of the Divisions was still going to be of enormous importance. It was the Division which would canalize the general feeling of practitioners at the periphery. One of its functions would be to prevent what he described as the splintering of the profession and to harmonize at the local level the work of general practitioners and of consultants and specialists.

Many questions relating to methods of conducting secretarial business were asked and answered. Some of the secretaries requested a more intimate method of communicating information, such as a revival of the Secretary's letter. Opinions were requested on possible improvements of the *Supplement*, but the only suggestion elicited was the old one, that the *Supplement* should be detached and have an exclusive circulation. The technical reasons against this were explained. Dr. FRANK GRAY (London) suggested that in future membership of the Division executive might well be considered as a step towards membership of the local medical committee.

Dr. A. S. WILSON (Holland Division) was unanimously elected chairman of the 1950 conference. Dr. PRIDHAM mentioned that the chairman of the conference would receive all the documents of the Organization Committee and be invited to attend its meetings, thus ensuring a closer liaison between Headquarters and the Secretaries Conference than had hitherto obtained.

Correspondence

Part-time Specialist Work

SIR,—Some years ago, at a time of anxiety, this country was assured by a statesman that his efforts would bring "peace in our time," a pronouncement soon proved to be merely wishful thinking and completely out of tune with the times. Now the best part of a year has passed since the hospitals of the country were taken over by the State under the National Health Service, accompanied by much publicity and trumpeting. At that time, and since, leaders of our profession hastened to assure the rank and file that all was well, and that as a result of their efforts they saw a future full of promise for all who whole-heartedly co-operated. But are we again to witness politicians' inability to control circumstances?

The Service has accepted the principle of continuance of some private practice. From the practitioner's point of view this appears secure in that his remuneration relates to the number of patients he attends under the Service and limitations are not imposed upon him preventing him from developing a certain, limited, private practice. Recently the proposals for the remuneration of consultants have been published, and our leaders and notably the medical press have hastened to say how generous the proposals are. Machinery for the paying of full- and part-time staff of specialist rank has been worked out to separate the personnel at specialist level into two groups—namely, full- and part-time.

The time has now come when regional boards are trying to fix hospital establishments. The power now lies in the hands of the bureaucrats as to whether they favour full- or part-time posts, for by their handling of hospital establishment part-time service and private specialist practice may perish. Where, for example, can a part-time specialist look for help for a private patient if he, engaged in part-time service, cannot look about him to obtain help from a part-time radiologist, radiotherapist, pathologist, bacteriologist, or biochemist, or even venereologist, in the area if the patient wishes to have a private-patient relationship with one of these, unless they too are on part-time work?

Clearly the trend is towards a full-time service. All young men will start their careers under full-time service, and part-time service can persist only if they are allowed to take up part-time posts as they get older. In the practice of medicine and surgery it would be a tragedy if promotion or retirement were conducted on the lines of the armed Services so that full-time workers, perhaps at the age when their energies were flagging, but certainly at the age when experience was most ripe, were retired to make way for younger men, as might be the case if it was full-time for all. Surely the more sensible and more economic method of stabilizing the profession would be by personal contracts so being arranged that a full-time worker could, as he gets older, reduce his contract to part-time so as, perhaps, in one case to protect his health, in another to take part in local government work or charitable or other public work not directly within his professional life. Can the present trend which we are witnessing be considered to make such transfer likely?

In actual fact a gulf has been put between full- and part-time work. A full-time worker is subject to regulations debarring him from certain privileges even outside his hours of contract. His pension is dependent upon his last three years' remuneration, which surely is a strong deterrent to reduction of working hours in the later years of life. If the future develops a scheme of mainly full-time clinicians, is it not likely that the responsibilities and strains of clinical life, so little appreciated by the office worker, will produce a generation of clinicians near retirement unable to keep up the pace, clinging, even against their will and perhaps in poor health, to full-time employment as the only alternative to complete retirement. Perhaps we will see them falling back on that so-called occupation of organization, which will all too frequently mean interference with the doctor-patient relationship of other specialists in a manner calculated to keep themselves as much as possible in the centre of things without exposing themselves to the full strain of clinical work.

Will it not be desirable to have some assurance from our leaders and from the Minister of Health as to the security in the future of private practice and part-time work? I suggest that it is necessary to have some guarantee of the following nature:

(1) That there is agreement between the Ministry and the profession that the principle of part-time work is to be encouraged and that there is opportunity for continuance of some private practice including the provision of some private beds.

(2) That the division between full- and part-time work be abolished together with the restrictions imposed upon full-time employment and that all consultants are offered a contract which can be varied up to a maximum of five-and-a-half days' work a week, and allowed to work outside these hours in a doctor-patient relationship without restriction.

(3) That the establishment of hospital staffs be kept fluid, so that when hospital appointments are made they are not made rigidly follow some established precedent, but are made to fill the need holding at that time; so that in practice a specialist holding part-time appointment may on retirement be replaced by a specialist holding a full-time appointment, or alternatively a specialist holding a full-time appointment may, if the local need justifies it, be followed by one holding a part-time appointment.

(4) That all appointments at specialist level are made accepting the principle that the individual has the option of being employed for less than a full working week if he so desires, or can exercise his option at some later date.

(5) That the pension machinery be reviewed to abolish the distinction between the present full- and part-time schemes.

I feel certain that the Royal Colleges and other leaders of our profession have been too interested in what happens in the centre of each Region and at teaching hospitals to inquire into the conditions under which the vast majority of specialists in this country, who are working in non-teaching hospitals, may be asked to work. I trust that the working members of the profession, looking for leadership to the Royal Colleges and to the British Medical Association, are not merely going to hear shouts of "security in our time" from men who have their eyes only on their next few years.—I am, etc.,

Nottingham.

A. N. BIRKETT.

Grading of Specialists

SIR,—I am instructed by my committee to send you a copy of the enclosed letter which has been sent to the Liverpool Regional Hospital Board:

"My committee wish to draw the attention of the regional board to the rising tide of indignation felt widely amongst the regional board's specialists at the method and results of the grading of specialists by the assessment committees in this region. Furthermore, we wish to draw attention to the following points:

"The use of the grades senior hospital medical officer and junior hospital medical officer to describe those performing specialist work. These grades have been applied to many persons holding specialists' appointments in regional board hospitals.

"There are many anomalies in the gradings which have been circulated, and it would appear that in particular insufficient weight has been given to specialist experience in the armed Forces."

—I am, etc.,

Liverpool.

V. COTTON CORNWALL,
Hon. Secretary, Liverpool Regional
Hospitals Medical Association.

Honour of Profession

SIR,—From reading the *Supplement to the Journal* and talking to my colleagues I find a great measure of agreement upon various matters in the new Health Service which require rectification. Apparently the majority of us think that 4,000 patients cannot be cared for properly by one doctor who also wishes to keep abreast of his medical reading, go to an occasional clinical or doctors' meeting, and have some leisure. It follows, of course, that we will require a much higher capitation rate if we are to have smaller numbers. The majority of us think that as mileage allowances stand at present a country or even a semi-urban practitioner is not being paid much more than half as well as a city doctor.

The younger men at least, both principals and assistants, are agreed that the present system which allows a doctor to hold 6,400 patients and pay a young doctor five, seven, or nine hundred a year to do half the work is far from satisfactory. We would all agree to an assistant being employed in order that an ailing doctor could carry on till his son took over, or to the case of a "trainee assistant" where there is likely to be "training."

There does not seem to be agreement among us one way or the other as to a sliding scale of capitation fees.

But far more important than any of those matters, and one which Mr. Bevan (Mr. Grant in Northern Ireland) would require to ponder over very seriously, is the fact that a gradual coarsening of the fibre of the general practitioner is at present in progress. It happens in this way: In the past week I have lost a patient who required me, without success, to give her posterior-pituitary extract for alopecia areata without specialist advice, another because I did not deal myself with a wart very near the limbus of the eye. An entire family left me because I could not get them coal.

I am at present waiting to find out if two insolent people will make good their threat of leaving me because I would not certify them as unfit to travel to the medical referee (in my area, there being no travelling medical referee, the certificate would have made them safe to continue to draw benefit).

I am continually being asked for single injections of penicillin, for jars of malt, certificates for corsets, certificates of incapacity when the illness is doubtful, letters requiring patients to be x-rayed for whatever they determine, and I know that, if I refuse, their cards will be transferred and they will have their demands fulfilled elsewhere.

It is a bitter experience for one who could not, and never would have the slightest desire to, earn his living away from medicine to feel that this professional prostitution is being forced upon him. Indeed, Sir—and the thought of it does not appeal to me—I am afraid that, if safeguards for our professional honour cannot be found within the present system, we will be forced in time into asking our Minister to convert us into a fully salaried Service.—I am, etc.,

CONN MCCLUSKEY.

Dungannon, Co. Tyrone.

Trainee Specialist Associations

SIR.—It is becoming apparent from the numbers of trainee specialist associations springing up all over the country that doctors in this category are aware of their present uncoordinated, unrepresented position, and are realizing that unless they help themselves no one else will.

At present the grading of posts, and of trainee specialists themselves, is going on without the methods and criteria by which these things are done being either uniform or public. Nor are trainee specialists themselves having any say in the matter except in the few areas where they are represented upon the medical advisory committees of their hospitals.

It is high time, therefore, for trainee specialists to organize themselves on a national basis so that their opinions may carry weight and that they may obtain the representation on medical committees in the National Health Service which their numbers and responsibilities justify.

It seems necessary that trainee specialist groups should be formed as soon as possible in every region, and I would be glad if anyone in this category wishing to form one in this region would get in touch with me.—I am, etc.,

20, Norham Gardens, Oxford.

H. A. W. FORBES.

The Dental Service

SIR.—My dentist, who recently entered the Health Service, has attended to my teeth for many years. He has by various forms of treatment kept my teeth and gums in good condition. He found, under the regulations of the Service, that he had to apply for special permission to be paid for this form of treatment. The reply was to ask for an examination by an inspector from the Dental Estimates Committee, and this duly took place. Now, although I was in my 68th year, I still had twenty-three teeth, many of them, of course, with fillings in them. The result of the inspector's examination was that he recommended that eighteen teeth should be removed. This included my nine remaining molars, which were quite useful teeth, and many of which my dentist held to be serviceable for a number of years. My dentist's reply was that he would absolutely refuse to do this, as he considered it dangerous to my health, was unnecessary, and also bad dental treatment. I quite agreed with him and told the inspector that I should on no account consent to such a procedure. I am in excellent health and there seemed absolutely no reason for removing the teeth. There was, it is true, alveolar absorption, but the gums were in a healthy con-

dition and the teeth were useful biting teeth. There was only one—under treatment—which was causing any active trouble, and also one which required to be filled. My dentist considered that it might cause very severe injury to my health to remove all these teeth, and I have personally known cases in which this occurred when a large number of teeth were removed.

Surely it is absolutely wrong that the Ministry officials should attempt to dictate to a dental surgeon what his treatment should be? If the Act leads to proceedings like this it must be a very bad Act.—I am, etc.,

London, W.1.

N. S. FINZI.

Discipline in N.H.S.

SIR.—(1) A doctor was held by a medical service committee to have given a patient pre-dated certificates (*Journal*, Feb. 26, p. 371); if true, an inexcusable, blameworthy, albeit what may be called a technical, offence. Penalty: 150 guineas fine and severe censure. Savage and senseless when compared with (2).

(2) A doctor according to the report (*Journal*, April 9, p. 638) was held by a medical service committee to have persistently failed to attend a small child when called. As a result it is alleged the child died of bronchopneumonia. Penalty: £10 fine and censure.

Comment on these two examples of disciplinary action is needless. If we are to be drilled and dragooned for all manner of things under the N.H.S. (and one does not dispute the need for it in the above two cases if the facts are true) let justice not only be done but let it also appear to be done.—I am, etc.,

Hove, Sussex.

G. L. DAVIES.

Steering Committee for Representative Meetings

SIR.—With the near approach of another Representative Meeting it is worth while considering whether these meetings can be made more satisfactory than they are, for I find after the score or so I have attended a fairly general feeling that a lot of time has been wasted. Some representatives also have a legitimate grievance that though their motions may have commanded general support they have been defeated for some technical reason or, more often, because they have embodied an unfortunate phrase or clause. There is also sometimes a feeling that the Agenda Committee has manipulated the result by the order in which notions have been discussed.

Now doctors are usually busy people, and some of us feel that no efforts should be spared to economize time and yet stimulate useful discussion of matters which concern us all vitally. Various steps have been taken towards this end by "starring" motions or by grouping them, but the ideal has not so far been reached. I would like to suggest the employment of a sort of "steering" committee, and after some experience of the way they work I would suggest the following.

The steering committee should consist of a few officials or members of the Council, who should from time to time throughout the meeting call together representatives supporting a group of motions dealing with a certain subject, together with one or two members of the Council particularly interested or briefed in that aspect of medical policy. These motions should then be discussed informally, and as a result the representatives would probably be able to agree among themselves on the best-worded motion to support, or perhaps they might frame an alternative resolution which would embody the general conclusion and at least not be technically invalid. The Council members would be able in private to give any required information to the representatives, so that a lot of time would not be wasted—as it often has been—through heated discussion due to ignorance or misconception of the facts.

No representative should be debarred from putting the special motion to the A.R.M. if he thinks it right to do so, but this preliminary discussion would prevent the interminable waste of time involved in putting almost similar motions, and also prevent the occasional seeming arbitrariness of the chairman in deciding on which of a similar series the discussion and voting should take place. It would put the proceedings much more in the power of the representatives and also ensure that those who propose resolutions are in possession of the necessary facts for their proper presentation.

Any motion so agreed upon in the steering committee should not be just formally put and passed without explanation.

indeed, it should be incumbent on the proposer to explain the point of his resolution and the objections and modifications urged against it. Having put the A.R.M. in possession of the salient facts it would then be open for any representative to speak as at present, and the chances are that by limiting the number of motions in this way fuller discussion would be promoted and important matters of principle properly ventilated and decided. As such, the results should be more worthy of our profession and of that humane temper and thorough examination of evidence that our work demands.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

Large and Small Practices

SIR,—In view of the many sharp divisions between men who run large practices and doctors who care for small ones, which it would seem, in answer to the Minister's dearest unspoken wish, are becoming a weekly feature of this and other columns, it would surely be wise to establish it as an axiom that the man with 2,000 patients runs his practice *himself*, and the man with 4,000 patients does not. This, in 19 cases out of 20, is fact, not argument; and, for better debate, it should be accepted as such by both sides before the shouting starts.

I have no doubt that the 4,000-plus man can run a practice "successfully"—that is, without killing his patients by neglect or himself by overwork. Indeed, with a small area to serve, a good secretariat, a State-subsidized assistant, and a brisk professional manner, he should have a shorter day than his brother in the country, for a large part of his daily work is in fact done for him by a drove of specialists and technicians, house-men, sisters, nurses, and medical students, all of whom, except the last, are separately paid by the State. The country doctor with a small list sends few of his patients to hospital or clinic, and, when he does so, often finds that it is to his colleagues or to himself that he has referred them.

There is room for both classes of doctor in the community; indeed, the 4,000-plus kind is in type the beau-ideal of the Welfare State. But it is to the country doctor with his smaller list, his greater distances, and his long working day that we owe our sympathy and support: sympathy and understanding if he sees in one who is paid twice as much for doing with outside help what he must do alone, a cross between a chemist's assistant and a reception clerk, with that most dangerous of vestiges—enough medical learning still clinging to his ink-soiled fingers to prompt an occasional and risky sortie into genuine medicine; practical support and sympathy from the lucky few who, like myself, are little affected by the sickle of reform; support and sympathy, in speech and writing, above all from the many who, by a stroke of luck and the passing of an Act, have been made financially secure for the first time. Let the Big Man in medicine new style, as, with his assistant "in" for him, he sits at ease before his television, instructing his secretaries, or chatting easily with his manicurist—let him spare a thought, a word, a letter on behalf of his brother in the country toiling late to bring cheer to some lonely farmstead and a crust to his wife and family. The fight for his welfare is on and he needs our help, not our rivalry.

To autocracy we have lost every battle; let us do our best to win this last.—I am, etc.,

Purley, Surrey.

GUY CARRELL.

Special Tax

SIR,—It is with great apprehension that I have read Dr. F. G. Wood-Smith's letter (*Supplement*, May 7, p. 266) suggesting that patients should pay to the doctor a flat rate of, say, 1s. per item of service. I believe that we should be absolutely overrun by our patients if this suggestion were adopted. Our patients have to overcome a certain amount of inhibition at present when they call on us. This hypothesis may be a little difficult to believe when one looks into the crowded waiting-room; however, it appears quite reasonable when one compares the number of calls to-day with the number of calls one year ago.

If the patient has to pay a fee to the doctor, I am certain that this inhibition will diminish reciprocally with the amount paid; our patients will feel that for 1s. or 2s. 6d. they can demand from us even more than they do now. I quite agree that a contributory payment at the time of attendance would deter the patients to a certain degree from abusing the Service,

but in my opinion they should contribute a certain percentage of the cost of the *prescribed medicine*, and this should be paid to the *chemist*.—I am, etc.,

Bristol.

PETER H. KEPPICH.

Assistantships

SIR,—As a previous letter of mine (*Supplement*, April 2, p. 216) in defence of the practice of employing assistants as a very good method of entry into practice has brought forth several replies, may I be permitted to answer two which appeared in the *Supplement* of April 23 (p. 250) signed "Another Assistant" and "X. Y. Z."?

My original letter was written in answer to a suggestion that all assistantships should be abolished as evil institutions. I am aware from what applicants for our own vacancy told us that there are many principals who are grasping, unscrupulous, and ill-mannered.

Because one occasionally hears of an immoral parson one does not condemn all parsons as immoral. An assistant's remedy is obvious: as soon as he becomes aware that his principal is not prepared to behave fairly he can give notice. My belief is that, in any populous area, a live assistant can soon increase a practice to provide a just claim for a partnership, and where accountants' figures show this the principal has no right to decline. If he pleads incompatibility of temperament he should have said so within a reasonable period.

To "X. Y. Z." I would say this. My reference to a man learning the intricacies of general practice did not refer to learning fresh knowledge of medicine and surgery. In fact I agree with his remark about "unlearning." When I left Guy's my physician made the remark that I knew more medicine and surgery than I should ever know again, but that in ten years I'd have learnt to be a "doctor."

The young man we have just admitted to partnership is good—very good. He is on the list of practitioner-obstetricians and has a very sound knowledge, yet he quite frequently has to ask help from my partner or myself because he lacks personal experience of dealing with people—the sick, their friends and lay advisers, relatives, and what not. It takes years to know what local consultants are most suitable to certain types, because consultants vary greatly, and to introduce the wrong type of surgeon or physician is often disastrous. As to all work and no pay, I know of no principal who pays less than £750 plus a house and often a car allowance.

But to my main points: how do these people suggest we should proceed? In the past one bought; that is all done away with except for one's house, but that is still one's own property and one can elect to remain in residence after disposing of one's practice. A death vacancy is advertised—many apply. Who is most likely to get it? Someone known locally or someone who knows someone who knows someone locally. Are the general run of young aspirants better off? "X. Y. Z." talks of "the hard way." I never found it so hard. I knew my obligations—the bank and finance company worked out that I'd have about £750 a year (pre-war) out of an income of £1,300 or so. But the practice just kept ahead and I never had so little as that even in the first year.

It seems to me it is now much harder to get established as a principal. It depends on chance. But take our own practice: if our new partner is really successful there is no doubt we shall need an assistant again, but this time we cannot offer a "view" unless and until the new assistant enables the practice to extend to provide for him. We are surrounded by six or seven other principals, and there must be a saturation point. Is this to exploit the young man who has so much to learn? I don't see it. If after a year or two he wishes to pass on to an assistantship with view, he will have learnt a great deal from a practice with 11,000 patients in a town with a large medical school with many well-known surgeons and physicians to call on in consultation.

No, Sir, the path of the assistant should be cleared of unnecessary obstacles. It should be an established custom for all principals with an assistant to have a quarterly audit, and, as soon as the returns show that the income has increased sufficiently, the assistant should have the right to claim a share. But assistantships cannot be abolished.—I am, etc.,

A. B. C.

Whither Medicine ?

SIR,—Lord Horder, in a dinner address to the West London Medico-Chirurgical Society on Feb 18 entitled "Whither Medicine?" (*Journal*, April 2, p 558) presents a very good case for the high moral ideals that the medical profession are aiming at. It should be read and studied by all thinking men and women, including politicians of all parties. I fully agree with "Medical Practitioner" (*Daily Telegraph* April 4) and Dr J P Matthews (*Supplement* April 2, p 216). These are extremely inspiring letters and express the views of many of us who have given the subject the serious consideration that it deserves.

Dr Semple, speaking at a general meeting of the Lincoln Division on March 17 (*Supplement*, April 9, p 228) asked: "Do we want lists of 4 000 and an early attack of coronary thrombosis, or lists of 2 000 and a high standard of medicine?" In my opinion this is no exaggerated statement. Many of us, though, are attempting a high standard of general and preventive medicine too, with what the B.M.A. calls the "average" list, and no private practice.

"Medical Practitioner" suggests two solutions to the problem that is facing our profession. Others have thought on similar lines hesitated to write the Press or the *Journal*, but have written to the Secretary of the B.M.A., Dr Charles Hill. The first is concerned with some method of improving the remuneration, and the other is "to educate the public by all the devices of propaganda, etc." I would also add, from personal experience, improvement of the hospital side of the Service. This does concern the general practitioner, and I write as a G.P. of many years' experience in an industrial district.

I cannot do better than draw the attention of your readers to what Lord Horder in his address calls the "basic needs" of the citizen and the doctor. "Medical Practitioner" does not state who is to "educate the general public in how the new Service should be used." Lord Horder suggests that if the politicians won't be guided we have "no alternative but to appeal to public opinion," continuing to serve the patient in the manner which the doctor believes to be in the patient's best interests.

I am in full agreement with that course but would wish to be more emphatic in our claims. In this connexion I am inclined to agree with the attitude of Dr John Hale Power whose letter also appears in the *Supplement* (April 2, p 215) with the exception that refusal to sign any State certificate would jeopardize the patient's best interest. Again quoting from Lord Horder's address: "We physicians must lead we must guide the politicians, since they cannot act without expert help, we must keep the citizen's end up, since he learns to rely upon us for support."

Finally, and most important of all problems, and mentioned by Dr. Matthews, is the apathy in the profession itself. I attribute this also to that "fed up" feeling due to the long-drawn-out negotiations but also to the lack of unity in the medical profession and the ability merely to "grouse" in private so beautifully put by one of the elders of the profession at a recent Divisional meeting: "We are all a set of twerps." I do not agree with the word "all." This remark was made after the meeting. Let us all speak freely at our Divisional meetings of our difficulties etc.

I wish to state that any observations I have made are purely in my capacity as a general practitioner with no other professional allegiance but to the B.M.A. for the past 27 years—I am etc.,

Leeds

HARRY SLGARE

Domiciliary Midwifery Payments

SIR—Dr Harris Avery draws attention to the discrepancy in midwifery payments (*Supplement* April 30, p 260), and points out that under the NHS scheme a fee of 7 guineas is payable for every booked case compared with the fee of 4½ guineas payable on a "medical aid," which usually involves more work for the doctor.

On the other hand there is a further discrepancy in which a practitioner called by a midwife to attend in connexion with an abortion or miscarriage receives 4 guineas, but under the NHS he would receive only 3½ guineas. No wonder there are some practitioners who having successfully applied to be

included on their obstetric lists have little interest in this side of medicine other than to be called in by a midwife to deal with a miscarriage. It is usually an easy 4 guineas.

These anomalies are presumably due to the Minister's inordinate haste to have the scheme ready for July 5 last—I am, etc.

Plymouth

C R BARKER

Charge Patients for Service

SIR—Some time ago (*Supplement* Dec 4, 1948 p 211) you published my letter regarding the suggestion that patients should pay 1s per service to the doctor. It now appears that the Government are considering some similar step in order to reduce the cost of the Service, but it seems to be their idea that the State should keep the shilling.

An opportunity like this is unlikely to occur again. The Government are in a mood to consider levying a charge per service. While this is so I would suggest that we offer to accept this charge in lieu of an increased capitation fee. It is said that we render 5-7 services per patient per year, which means on an average that the charge would be equivalent to a 6s increase in the capitation fee. Counting 40 million people as being in the Service, this is equal to an increase in the pool of 12 million pounds a year—which is roughly the increase we need to bring the betterment factor up to 170%.

This system would have many advantages:

- (1) Patients would appreciate the Service more by having to pay a little, and the weekly cough bottle types would dwindle in numbers.
- (2) Remuneration would be more adequate without cost to the State.
- (3) The excellent principle of more work more pay would apply a little more markedly.
- (4) Costs over the G.P. service as a whole would fall, as prescribing would diminish.

Could there be a more fair and reasonable solution of ours and the Government's problems?

Further, as regards a sliding capitation fee, this could then be applied to our present one if it were still felt that smaller lists needed further assistance, and in this respect, in my view, the more that is put on the first thousand the better, as average lists are sure to fall when the number of doctors increases as increase they will in the next 10-20 years. The more there is on the first thousand the less will our individual incomes fall in the future. Action will, however, have to be swift before Sir Stafford Cripps makes up his mind—I am, etc.

Leeds

S A SMITH

The Amending Bill

SIR—The National Health Service Act was described recently by a High Court judge as a miracle of ineptitude. The Minister of Health promised us doctors that he would introduce an amending Bill, and that he would give us doctors an opportunity of discussing with him and his officials the proposed amendments to be introduced in the Bill before it was finally drafted for presentation to Parliament. This he has failed to do, and the amending Bill has now been tabled.

This amending Bill can only be described as a miracle of easiness and bluff. Many of us G.P.s cast our minds to the early 1920's, when after repeated attempts to obtain better remuneration the old Insurance Acts Committee—now the General Medical Services Committee—called for mass resignations of doctors serving under the N.H.I.—got them and held them—to be used if doctors' terms of service were not improved and better pay given for work done. The result we all know.

The position now is exactly comparable to that existing then in the early 1920's, and similar action is called for. Let us waste no more time. We want deeds not words—I am, etc.,

Leeds

H VICKERS

FEES FOR FIRST-AID LECTURES

It is stated in paragraph 85 of the Annual Report of Council (*Supplement* April 2, p 174) that the St. John Ambulance Association has adopted the mileage rate of 1s a mile (each way) beyond two miles. The British Red Cross Society informs us that it also adopted this mileage rate when the fees for lectures and examinations were increased.

H.M. Forces Appointments

ROYAL ARMY MEDICAL CORPS

Lieutenant-Colonels L. S. C. Roche, H. W. Daukes, and R. R. Leaning, O.B.E., have retired on retired pay and have been granted the honorary rank of Colonel.

Lieutenant-Colonel H. Clain has retired on retired pay on account of disability. (Substituted for the notification in a *Supplement* to the *London Gazette* dated Feb. 8.)

Major H. A. Ferguson, retired, re-employed, has been restored to the rank of Lieutenant-Colonel on ceasing to be re-employed and has been regranted the honorary rank of Colonel.

Majors R. E. Waterston, H. N. Perkins, R. J. G. Morrison, J. W. Orr, M.C., and J. L. Gordon, O.B.E., to be Lieutenant-Colonels.

Major D. J. H. Jones has retired on retired pay and has been granted the honorary rank of Lieutenant-Colonel. (Substituted for the notification in a *Supplement* to the *London Gazette* dated July 9, 1948.)

Major J. A. Davidson has retired, receiving a gratuity, and has been granted the honorary rank of Lieutenant-Colonel.

Major J. Davidson has relinquished his commission, retaining the rank of Major.

Major G. L. Ritchie has been restored to Establishment.

Temporary Commissions.—Majors R. S. de C. Bennett and J. H. Robinson have relinquished their commissions, retaining the rank of Major.

Major J. A. Manifold has been seconded with the Foreign Office. Captains C. C. Corfield, J. H. Brodie, and H. M. Upshon to be Majors.

Short Service Commissions.—Captain W. S. Rhodes has retired, receiving a gratuity, and has been granted the honorary rank of Major. Captain S. J. Nathan to be Major.

Short Service Commissions (Type "B").—Majors H. Shield, M.C., T.D., from T.A., and S. J. Nathan, R.A.R.O., to be Majors.

Women's Forces Employed with R.A.M.C.: Short Service Commission (Type "B").—Captain (Mrs.) H. McKendrick to be S. Commander.

REGULAR ARMY RESERVE OF OFFICERS

Major-Generals O. Ievers, C.B., D.S.O., F. D. G. Howell, C.B., D.S.O., M.C., F. Casement, D.S.O., W. B. Purdon, D.S.O., O.B.E., M.C., H. H. A. Emerson, C.B., D.S.O., and T. S. Coates, C.B., O.B.E., late R.A.M.C., having exceeded the age limit for liability to recall, have ceased to belong to the Reserve of Officers.

Colonels (Honorary Brigadiers) C. C. Crawford-Jones, C.B.E., A. A. M. Davies, R. K. Mallam, O.B.E., E. U. Russell, M.C., A. D. Stirling, D.S.O., and J. B. A. Wigmore, late R.A.M.C., having exceeded the age limit of liability to recall, have ceased to belong to the Reserve of Officers, retaining the honorary rank of Brigadier.

Colonels A. Dawson, O.B.E., L. Dunbar, O.B.E., A. Jackson, E. C. Lang, D.S.O., W. F. M. Loughman, M.C., L. Murphy, D.S.O., R. E. U. Newman, C.B.E., M.C., S. D. Reid, J. Rowe, O.B.E., M.C., G. F. Rudkin, D.S.O., E. D. K. Seaver, R. W. Vint, and J. M. Weddell, C.B.E., late R.A.M.C., having exceeded the age limit of liability to recall, have ceased to belong to the Reserve of Officers.

INDIAN MEDICAL SERVICE

Colonel A. V. Lopes has retired.

Lieutenant-Colonels J. McM. Wilder and E. G. Hurd-Wood have retired and have been granted the honorary rank of Colonel.

Lieutenant-Colonels R. A. Wesson and W. J. Webster, C.I.E., M.C., have retired.

Majors J. G. Thomson, D. G. McCauly, and W. H. A. Thorne, O.B.E., have retired and have been granted the honorary rank of Lieutenant-Colonel.

Majors A. H. Barzilay, D. McCarthy, J. O'Neill, R. J. Jarvie, M. M. Mansfield, M. K. Bryce, W. J. Stewart, R. I. Reid, and F. C. Jackson to be Lieutenant-Colonels.

Major A. M. McGavin has retired.

Captains E. L. Wilson, H. C. Rogers, J. J. Woodward, S. H. Heard, M.B.E., J. E. Ennis, R. D. D. Birdwood, M.C., J. M. M. Drew, O.B.E., R. M. McCullough, H. V. Morris, F. W. Snedden, O.B.E., J. L. M. Whitbread, S. G. Nardell, L. E. Elkerton, H. F. T. MacFetridge, D.S.O., P. M. Kirkwood, M.B.E., W. D. P. Griggs, G. S. Michelson, P. W. Kent, R. O. Yerbury, J. P. O'Riordan, H. Rees, D. F. Eastcott, W. S. Hacon, and L. H. Cooper to be Majors.

Captain N. C. Todd has retired and has been granted the honorary rank of Major.

EMERGENCY COMMISSION

Major E. L. Jones has relinquished his commission and has been granted the honorary rank of Lieutenant-Colonel.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar, Non-County Borough Councils.—Dartford, Wallsend.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huyton-with-Roby, Redditch (restricted to new appointments), Tyldesley.

Association Notices

GROUP OF DERMATOLOGY

A conference of members of the Group of Dermatology will be held at B.M.A. House on Thursday, June 16, 1949, at 2 p.m. to receive a report from the Group Committee and to discuss matters of interest to members. All members of the Group are invited to attend.

ELECTION OF MEMBER OF COUNCIL, WEST INDIAN GROUP OF BRANCHES, 1949-52

The following is the result of the election for a member of Council by the Grouped West Indian Branches, 1949-52:

H. B. Morgan (London)	77 votes (elected)
J. B. Wrathall Rowe (Harrow)	37 votes
No. of voting papers issued	361
No. returned	114

CHARLES HILL,
Secretary.

Diary of Central Meetings

MAY	
31 Tues.	International Relations Committee, 2 p.m.
JUNE	
2 Thurs.	General Medical Services Committee, 11 a.m.
2 Thurs.	Proprietary Medicines Committee, 2 p.m.
2 Thurs.	Joint Committee of the B.M.A. and National Veterinary Medical Association, 3 p.m.
3 Fri.	Committee on Psychiatry and the Law, 2 p.m.
9 Thurs.	Publishing Subcommittee, 11 a.m.
10 Fri.	Library Subcommittee, 12 noon.
10 Fri.	Science Committee, 2 p.m.
10 Fri.	Public Health Committee, 2 p.m.
16 Thurs.	Dermatologists Group, Committee, 11.30 a.m.
16 Thurs.	Group of Dermatology Conference, 2 p.m.

Branch and Division Meetings to be Held

BOLTON DIVISION.—At Bolton Royal Infirmary, Tuesday, May 31, 8.30 p.m., annual general meeting. Consideration of Annual Report of Council, election of officers, etc.

EAST HERTS DIVISION.—At County Hospital, Hertford, Thursday, June 2, 8.30 p.m., annual general meeting.

LEICESTERSHIRE AND RUTLAND BRANCH.—At Nurses' Recreation Room, Leicester Royal Infirmary, Wednesday, June 1, 8.30 p.m., annual general meeting. Address by Dr. E. Grey Turner.

METROPOLITAN COUNTIES BRANCH.—At B.M.A. House, Tavistock Square, London, W.C., Tuesday, June 7, 2.30 p.m., annual general meeting. Agenda: Induction of Dr. C. G. Martin as President of the Branch and President's Address, etc.

MID-ESSEX DIVISION.—At Chelmsford and Essex Hospital, Sunday, May 29, 10 a.m. Dr. R. Sleigh Johnson: "Streptomycin in the Treatment of Chest Diseases."

NORTH-EAST SUFFOLK DIVISION.—At Nurses' Lecture Room, Lowestoft and North Suffolk Hospital, Sunday, May 29, 3 p.m., annual general meeting. Consideration of Annual Report of Council of B.M.A. (*Supplement*, April 2, p. 174), etc.

OXFORD DIVISION.—The Oxford Division is celebrating the centenary of the birth of Sir William Osler on Tuesday, July 12. The programme includes a medical meeting in the Sir William Dunn School of Pathology at 2.15 p.m., when Lieutenant-General Sir William MacArthur and Sir Henry Cohen will speak; tea in Osler House at 4.30 p.m.; and a dinner in Christ Church at 7.30 p.m., at which Professor J. A. Ryle will propose "The Art and Science of Medicine," Sir Hugh Cairns "Sir William Osler," and the Regius Professor of Medicine, Professor A. D. Gardner, "The Guests." The price of the tea is 2s. per head and that of the dinner £1 12s. 6d. A limited number of tickets are still available, and anyone wishing to attend should write at once to Dr. C. W. M. Whitty, 121, Woodstock Road, Oxford.

WANDSWORTH DIVISION.—At Stanley's Masonic Halls, 51, Lavender Gardens, Lavender Hill, London, S.W., Tuesday, May 31, 8.30 p.m. Annual meeting. Election of officers, etc.

WINCHESTER DIVISION.—Wednesday, June 1, (1) At Royal Hampshire County Hospital, 3 p.m., clinical meeting. Address by Mr. A. M. A. Moore: "Applied Anatomy in General Practice"; (2) At Norman Mede Hotel, 7 p.m., annual meeting; 8 p.m., chairman's sherry party; 8.30 p.m., dinner. Talk by Dr. S. J. Hadfield: "Current Events."

RETURN TO PRACTICE

The Central Medical War Committee announces that Dr. A. W. J. Houghton, M.R.C.P., Draper's Hall, Shrewsbury (Shrewsbury 2129), has resumed civilian practice.

SURGICAL ASPECTS OF MENINGITIS*

BY

Sir HUGH CAIRNS, K.B.E., D.M., F.R.C.S.

Nuffield Professor of Surgery, University of Oxford

There is general agreement that in the last 50 years adequate surgical treatment of infections of the middle ear and mastoid has greatly reduced the incidence of meningitis and other intracranial infections. This can be confirmed by comparing cases of the present day with those described by William Macewen in his classic work, *Pyogenic Infective Diseases of the Brain and Spinal Cord*, published in 1893. Similarly, improved surgical cleansing and suture of open wounds of the head have effectively prevented many cases of meningitis. These facts are so well known that all that is necessary here is to remind ourselves what a valuable procedure it can be to release pus from the ear by prompt incision of the ear-drum or to spend time in careful treatment of the simple scalp wound.

Historical

Horsley (1890) seems to have been the first in modern times to operate for meningitis; a year before lumbar puncture was introduced he established continuous drainage of the cerebrospinal fluid (C.S.F.) through a laminectomy wound; and he also irrigated the subarachnoid space with weak bichloride of mercury. About the same time Mayo-Robson (1890) and others drained the lateral ventricles. These pioneer efforts were important for the development of neurosurgical technique, but did not save lives.

Surgical methods were employed for three main purposes: (1) the application of antiseptics and antisera; (2) drainage of C.S.F., continuous or intermittent; and (3) irrigation of the cerebrospinal pathways with "physiological" fluids. The only antibacterial substance whose use seems to have been attended by any success was Flexner's meningococcal antiserum. It was introduced into the lateral ventricles (Cushing and Sladen, 1908) and later, with more success, into the cisterna magna (Ayer, 1920): the advantage claimed over these routes over the usual lumbar route was that the serum might more easily spread to all parts of the cerebrospinal pathways, especially when there was a spinal block.

Dandy (1924) concluded that antiseptics were of no value or pyogenic meningitis, but wrote: "Despite past and present failures, one cannot but feel that the future treatment of septic meningitis may yet lie in antiseptics or sera. Though seemingly impossible from our present knowledge, the detection of a specific antiseptic or of a specific serum so accurately balanced as to be without injury to the naked nervous system seems no more unlikely than Flexner's remarkable antimeningococcal serum, or the recent brilliant discovery by Sicard that lipiodol could be injected into the subarachnoid space, cast a dense shadow, and still be harmless to the delicate host."

Continuous drainage from the cisterna magna or lumbar subarachnoid space was tried by a number of workers (Dandy, 1924; Spurling, 1928; Thompson, 1937), while a few favoured continuous ventricular drainage, particularly when hydrocephalus was developing (Hampson, 1935). The reasons advanced for drainage were: to provide exit for the inflammatory products; to reduce intracranial pressure; and to promote increased flow of C.S.F. and thus to dilute the toxins. Kubie (1928) advocated that during drainage large amounts of hypotonic fluids should be given by vein or subcutaneously, as well as water by mouth, to promote the flow of C.S.F.

Irrigation with Ringer's solution was tried—from lumbar region to cisterna magna (Murphy, 1907), from ventricles to the lumbar subarachnoid space (Day, 1913), and from cortical subarachnoid space to cisterna magna (Eagleton, 1921)—but without any clear evidence of benefit; though Hampson (1935) mentioned a case in which, after blocking at the foramen magnum by presumed tonsillar cone, the flow of C.S.F. was re-established by instilling fluid into the lumbar space under positive pressure while intracranial pressure was reduced by ventricular drainage.

In small groups of cases good results were reported after the use of one or more of these methods, and in meningococcal meningitis the results in larger series indicated a modest improvement on what had been obtained before (Ayer, 1920; Hampson, 1935; Tripoli, 1936). However, the "surgical" methods were not generally adopted, and their use in acute meningitis was largely abandoned as soon as sulphonamides showed their worth—an event which indicates that the subject of meningitis is dominated by bacteriological considerations and that surgical methods can play but a subsidiary part. Destroy the bacteria, and the inflammatory products and toxins can be looked after by the meninges without drainage of the C.S.F. or irrigation of its pathways.

Since the advent of penicillin in 1942 there has been a revival of surgical methods of treatment; for penicillin does not pass the blood-C.S.F. barrier in sufficient amount, and thus must be directly introduced. Surgical methods have also proved their worth in the application of streptomycin; though in the case of this drug it is difficult to understand why the intrathecal route should be necessary, as it clearly is, since good levels of streptomycin in the C.S.F. can be obtained by intramuscular administration alone.

Post-operative Meningitis.—The interests of the neurosurgeon in meningitis develop naturally from his concern to prevent meningitis after head wounds or "clean" operations such as removal of cerebral tumour. When the first cerebral glioma was removed by Godlee in 1884, "a slow

*University of London Lecture delivered at Westminster Hospital on Feb. 10, 1949.

infection of the wound occurred, and after four miserable weeks of disappointed hopes the patient died of meningitis" (Trotter, 1934). At one time in my practice one-quarter of the operative deaths were from intracranial infection, in particular from meningitis (Cairns, 1939b). The local application of penicillin before closure of the wound has reduced the incidence of infection in our major cerebral and spinal operations from 4.4 to 0.9% (Pennybacker *et al.*, 1947). This subject need not be considered in detail, but there are a few points of general application.

Pathology and Anatomy of Meningitis

I do not propose to describe the pathological anatomy of meningitis, but rather to touch upon some aspects of it which arise from surgical experience.

I. The Resistance of Brain Tissue to Infection

From our work on operative infections we concluded that the brain itself is relatively resistant to bacterial infection, whereas the large cerebrospinal pathways—the ventricles and basal cisterns—are much more prone to become infected.

1. Culture plates exposed in the operative field always yielded bacterial growth and showed that even with the most careful aseptic technique it is impossible to prevent bacterial contamination of the wound during long intracranial operations (Cairns, 1939b).

2. On occasions cocci have been seen in films and cultures of material aspirated from the bed of a cerebral tumour in the first days after operation, yet no sepsis has developed.

3. In the days before penicillin the incidence of infection after posterior fossa operations was 1 in 12, all of them cases of meningeal infection, whereas after operations on the cerebral hemispheres it was 1 in 30, and the majority of these were infections of the bone and scalp (Pennybacker *et al.*, 1947). In other words, most of our cases of intra-cranial infection have been cases in which there was a wide opening of the arachnoid cisterns or ventricles, though it is likely that just as many bacteria fell into the brain tissue as into the cerebrospinal spaces.

The relative resistance of the brain tissue, which may be due to the speed with which large numbers of microglial phagocytes gather at any injured part of the brain, may account for the remarkable freedom of the brain tissue from gross infection in many forms of non-surgical leptomeningitis. In pyogenic meningitis bacteria often get into the brain as well as into the leptomeninges; for example, in pneumococcal meningitis they can be seen at necropsy in the brain tissue itself beneath the pia-arachnoid and around the walls of the ventricles, yet in the cases which survive an early death abscess within the brain is an event of great rarity. Furthermore, drainage or excision of an abscess of the cerebral hemisphere is rarely followed by meningitis, although the brain must often be contaminated at the time of operation.

It is astonishing to see what a perfect intellectual recovery can often follow the most intense meningitis. In most bacterial infections of the leptomeninges it seems as though the brain looks after itself. Indeed, as regards subsequent brain function the complication most to be feared is arteritis of the penetrating vessels, with resultant cerebral infarction, rather than any purulent cerebritis (Cairns and Russell, 1946; Daniel, 1949).

II. "Saprophytic" Bacteria May Produce Meningitis

From our operative infections we have also learned that bacteria which are supposedly saprophytic to man may set up severe and even fatal meningitis and ventriculitis (Cowan, 1938); such organisms as *Micrococcus tetragenus*, *Diplococcus mucosus*, *achromobacter*, *Staphylococcus albus*, and

certain Gram-negative bacilli. In these infections the general symptoms may at first be slight, and so also is the cellular reaction in the C.S.F. But the meningitis is of an adhesive type: it blocks the cerebrospinal pathways and thus produces progressive hydrocephalus, perpetuating the lesion for which operation was undertaken in the first instance. This slow progressive post-operative meningitis has become less common since the introduction of antibiotics, a point confirming its bacterial origin, for some were wont to regard it as "aseptic meningitis."

The condition is important in adding to our understanding of certain cases of spontaneous progressive hydrocephalus of infective or probably infective origin (Dott and Levin, 1936). In these cases there is often no initial acute illness or obvious history of meningitis, and the case may masquerade as non-infective hydrocephalus. But in her important review of the pathology of hydrocephalus Dorothy Russell (1949) has shown that at least some of them are of bacterial origin.

III. The Influence of Raised Intracranial Pressure

In the acute stage of any form of meningitis intracranial pressure is raised. This rise of pressure is not usually an important cause of symptoms in the early stage—that is, before there has been time for adhesions to form—though it may become so later. In tuberculous meningitis we tried continuous drainage of the lateral ventricles in the acute stage in the hope of lessening the coma and other severe symptoms. There was no improvement; Dandy (1924) had the same experience on draining the cisterna magna in acute purulent meningitis.

In tuberculous meningitis we also found that withdrawal of the ventricular C.S.F. at its source was immediately followed by a very great rise of the protein content of the lumbar C.S.F. (from 100 to 4,000 mg. per 100 ml.) (Fig. 1) and an unusually early deposit of fibrin in the cisternae ambiens and interpeduncularis. Evidently, if C.S.F. is to be drained away in the acute stage of meningitis it should, if possible, be taken from the site of maximum inflammation and not from the ventricles. The diluting action of the newly formed ventricular fluid with its small protein content is probably useful in preventing deposition of fibrin and pus, with blockage of the cerebrospinal pathways. I must emphasize that these conclusions relate only to the acute stage: ventricular drainage may be of great value in the subacute and chronic stages of meningitis.

FIG. 1.—Two cases of tuberculous meningitis, showing rise of protein in lumbar C.S.F. following continuous drainage of lateral ventricle.

IV. Blockage of the Cerebrospinal Pathways

Any part of the cerebrospinal pathways may become blocked in meningitis, but this is not serious unless it affects the main bottlenecks and thus interferes with the onward flow of the bulk of the cerebrospinal fluid. The blockage may be due to fibrin and inspissated pus or to granulation

tissue in various stages of organization, and symptoms may arise during the stage of active infection or subsequently. In the latter case the stage of active infection may have been inconspicuous, or it may have occurred many years before the onset of symptoms of obstruction. Thus, Baker (1934) reported a remarkable case of death from hydrocephalus after three weeks' illness in a girl of 17 who had had meningococcal meningitis at the age of 18 months.

FIG. 2.—Sites of obstruction of cerebrospinal pathways. (1) Foramen of Monro; (2) aqueduct of Sylvius; (3) foramen of Magendie (and foramina of Luschka); (4) cisterna ambiens; (5) spinal subarachnoid space.

The main sites of obstruction are: (1) foramen of Monro, (2) aqueduct of Sylvius, (3) foramina of Magendie and Luschka, (4) cisterna ambiens, and (5) spinal canal. (Fig. 2.) It is possible also that obstruction as a result of meningitis might take place at the arachnoid granulations alongside the venous sinuses, but we have not obtained any convincing proof of that.

At the first three sites mentioned obstruction prevents the escape of C.S.F. from the ventricular system, with the result that there is little C.S.F. in the lumbar subarachnoid space, and the spinal pressure may fall. Dyes or antibiotics injected into the ventricles cannot be detected in the spinal C.S.F., and passage in the reverse direction is also blocked. These obstructions give rise to what Dandy (1918) called "obstructive hydrocephalus." On the other hand, if the obstruction is in the cisterna ambiens at the tentorial opening, C.S.F. escapes from the ventricular system and distends the infratentorial basal cisterns and spinal subarachnoid space, but cannot reach the subarachnoid space over the cerebral hemispheres whence it is absorbed. There is then abundant fluid on lumbar puncture, and dyes or antibiotics injected into the ventricles pass freely into the spinal C.S.F. This condition Dandy termed "communicating hydrocephalus."

Obstruction of the spinal subarachnoid space does not interfere seriously with the circulation of the C.S.F. or cause rise of intracranial pressure, but it is important in preventing antibiotics administered by the lumbar route from reaching the cerebral subarachnoid spaces and ventricles. Spinal block can be easily studied in life, and thus provides us with an indication of the course of subarachnoid obstructions in general.

From daily lumbar puncture in our cases we have learned that the obstruction may be incomplete; that it may disappear within 24 hours or last several weeks or even longer; and that there is a strong tendency for it to disappear long before all the inflammatory granulation tissue has resolved.

V. Foraminal Herniations of Brain Substance

In the obstructions which produce rise of intracranial pressure a complicating factor is introduced by herniation of parts of the brain through foramina, such as the foramen magnum and the tentorial opening. These obstructions have been mainly studied in relation to intracranial tumours (Spatz and Stroescu, 1934; Vincent *et al.*, 1936; Jefferson, 1938; Cairns, 1939a), but the same factors may operate in meningitis (Hampson, 1935).

When the lateral ventricles are dilated the hippocampal gyri tend to be displaced into the tentorial opening (Fig. 3) and thus may convert a partial obstruction of the cisterna ambiens into a complete one. When the foramina of Magendie and Luschka are obstructed the fourth ventricle dilates, with displacement downwards of the cerebellar tonsils through the foramen magnum (Fig. 4), thus perhaps converting a partial block into a complete one, or adding yet more compression upon

FIG. 3.—Downward herniation of temporal lobe through the tentorial opening.

FIG. 4.—Downward herniation of cerebellar tonsils through the foramen magnum.

FIG. 5a.—Upward herniation of cerebellar vermis through tentorial opening in a case of communicating hydrocephalus due to occlusion of the cisterna ambiens by tuberculous granulation tissue.

FIG. 5b.—Normal tentorial opening. For comparison.

the adjacent medulla oblongata; or the cerebellar vermis may be displaced upwards through the tentorial opening, adding obstruction of the subarachnoid bottleneck around the midbrain to the already existing obstruction at the exits of the fourth ventricle. This type of obstruction is also seen in communicating hydrocephalus from obstruction of the cisterna ambiens (Figs. 5a and 5b).

These additional obstructive factors may operate intermittently, with corresponding fluctuations in the clinical state of the patient. At an early stage the brain herniation can be relieved by one or more ventricular tapplings, and the patient may thus be tided over a dangerous period of obstruction. At a later stage the herniated brain may become impacted and then, though dangerous symptoms may be circumvented by continuous ventricular drainage, the patient usually dies from compression of the brain stem. Death is often quite sudden, the clinical events leading up to it being inconspicuous.

VI. Relapse

Relapse has long been recognized as a feature of meningococcal meningitis, and since other varieties of meningitis have been brought under control by sulphonamides and antibiotics they also have been shown to relapse. Thus it has been seen at Oxford in a high proportion of cases of pneumococcal meningitis (Smith *et al.*, 1946a), in meningitis due to *Pseudomonas pyocyanea* and other Gram-negative saprophytes (Lewin and Vollum, 1948), in tuberculous meningitis (Cairns and Taylor, 1949), and in influenzal meningitis (Neligan and Ounsted, 1949—personal communication).

Relapse or recurrence of meningitis may be due to infection from without, as in certain cases of chronic pneumococcal infection of the petrous bone and overlying dura, or to repeated infections through fractures involving the

paranasal sinuses with tearing of the overlying dura. More commonly it is due to recrudescence of an infective focus within the central nervous system. These foci are minute abscesses, or collections of fibrino-purulent material containing bacteria in the subarachnoid space (Smith *et al.*, 1946a, Fig. 3) or within the lateral ventricle (Fig. 6); or, in the case of

FIG. 6.—Fibrino-purulent clot containing Gram-positive cocci, in posterior horn of lateral ventricle in a case of pneumococcal meningitis after head injury. The patient was recovering from his first attack of meningitis, when he died of traumatic fat embolism.

tuberculous infection, fibrino-caseous material containing bacteria in the meninges or brain (Fig. 7).

The power of antibiotics to penetrate such non-vascular areas of infection is very limited, and the appropriate antibiotic must therefore be maintained in the C.S.F. until the fibrinous area has been completely absorbed, with release of all its bacteria, or until the lesion has become organized or enclosed in dense fibrous tissue, as may happen in tuberculous meningitis. This principle is important in the treatment of all cases of meningitis which are prone to relapse. In tuberculous meningitis, a disease which under treatment runs a very slow course, streptomycin must be maintained in the C.S.F. for many months.

FIG. 7.—Fibrino-caseous material containing numerous acid-fast bacilli in cisterna ambiens. From a case of tuberculous meningitis which was fatal on the 70th day of streptomycin treatment. (Diagram by Dr. Dawn Bosanquet.)

The Part of Surgical Operations in Meningitis

Operative procedures may be undertaken in connexion with meningitis for the following reasons: to prevent meningitis, to assist in rapid diagnosis of meningitis and of some of its complications, for the introduction of antibiotics, and to relieve or circumvent obstruction of the cerebrospinal pathways and the associated rise of intracranial pressure.

Prevention of Meningitis

The importance of prompt surgical treatment of scalp wounds and infected ears has already been mentioned. During the recent war, as a result of segregation and follow-up of Service patients with head injuries, we learned that meningitis was more common after head injury than we had formerly thought, and especially after fractures of the anterior fossa. Further evidence on this point was forthcoming when patients with pyogenic meningitis began to recover as a result of penicillin treatment. Five of our first 38 cases of pneumococcal meningitis followed head injury.

Case Report

A man aged 44 (No. 20301/43) was admitted in a confused but not comatose state to the Radcliffe Infirmary on Dec. 17, 1943, on the third day of an attack of pneumococcal meningitis. He was treated with penicillin intrathecally and intramuscularly and made a prompt recovery. By Dec. 27 he was lucid, and neurological testing showed severe hyposmia, which he said dated from a head injury due to a motor-cycle accident some seven years before. Inquiries revealed that at that time he had had a bruise on the left eye and temple with epistaxis, but no fracture had been seen in the radiographs, and there had been no leakage of C.S.F. from his nose.

The story suggested that his meningitis might have resulted from bacterial infection through an old fracture involving the paranasal sinuses. Radiographs taken after he had recovered from the meningitis showed no definite signs of an old fracture, but it was thought that there might be a deficiency in the posterior wall of the left frontal sinus. At operation on Feb. 15, 1944, the left side of the anterior fossa was explored intradurally through a frontal osteoplastic flap. No abnormality was found in the dura over the left frontal sinus, but further back, over the ethmoidal sinus region, there was a smooth-edged cleft (1 by 0.3 cm.) in the dura into which passed a diverticulum of arachnoid, of the inferior surface of the left frontal lobe (Fig. 8). This was evidently the remains of a brain herniation through a dural tear and fracture at the time of the head injury seven years before, but all that it now contained was a leash of small blood vessels and some C.S.F. When the vessels had been divided and the sleeve of arachnoid had been detached from the bone it was possible to pass a probe down into the ethmoidal sinus. The cleft was closed with a graft of temporal fascia.

The patient made an uneventful recovery and returned to work in April, 1944. During the next five years, up to the time of his last report in February, 1949, he had remained well and at work, though suffering occasionally from headaches.

FIG 8.—Dural tear and fracture into the left middle ethmoidal sinus. Repaired with graft of fascia lata.

I have seen meningitis develop at all stages between one day and 10 years after fractures of the anterior fossa involving the paranasal sinuses, with tearing of the overlying dura. Thus no one with an unclosed dural tear over a fractured ethmoid or frontal sinus can be regarded as safe from this risk. The meningitis, usually pneumococcal, may follow a cold in the head, but often it comes when the sinuses are not infected. In certain cases it is easy to predict the presence of a dural tear: cases with persistent cerebrospinal rhinorrhoea or with intracranial aerocele after head injury (Cairns, 1937), or cases like that just described in which there has already been one attack of meningitis. But there are other patients with anterior fossa fracture and loss of smell, but no rhinorrhoea or aerocele, who will get meningitis at some future time if a dural repair is not carried out. Much work was done on these cases during the war (Cairns, 1942; Calvert, 1942, 1947; Stewart and Botterell, 1947; Johnson and Dutt, 1947). Successful diagnosis depends largely on the radiographic evidence of fracture lines across the anterior fossa, and interpretation of these is still very difficult.

Fractures of the middle cranial fossa may establish a connexion between the middle ear and the subarachnoid space and thus give rise to meningitis, with or without escape of C.S.F. from the ear. In these injuries, other than those due to gunshot wounds, meningitis usually arises within the first few weeks if at all. In blunt injuries the path between ear and brain usually closes spontaneously. But after gunshot wounds operative dural repair may be necessary (Johnson and Dutt, 1947).

While on the subject of meningitis after head injury I must mention an uncommon complication which requires urgent surgical intervention. In a few cases the escape of C.S.F. from the nose may be so profuse that it is impossible to maintain an adequate level of penicillin in the C.S.F. by the usual intrathecal dosage. If meningitis has already begun in such a case it may be necessary to give penicillin by lumbar puncture twice or thrice daily in the usual doses, and to operate to close the C.S.F. leak immediately the acute stage of the meningitis has been overcome.

Diagnosis of Meningitis

Ventricular estimation and ventriculography are sometimes important in diagnosis. Now that there is an effective treatment for most varieties of meningitis, early diagnosis has become a matter of great importance. The advice of Goodhart and Still (1913) on the diagnosis of tuberculous meningitis—to wait for the disease to declare itself—is no longer sound. Every hour of delay in applying the appropriate antibiotic intrathecally seriously diminishes the patient's chances of recovery. To arrive at the correct

diagnosis there is no need in most cases to employ operative methods; all that is required is lumbar puncture and bacteriological examination of the C.S.F., the whole procedure being carried through with all the sense of urgency that would be applied to the investigation and treatment of a patient with perforated duodenal ulcer. But in some cases the diagnosis cannot be quickly solved without the use of ventricular estimation or ventriculography.

For example, if the meningitis begins with focal symptoms and raised intracranial pressure, as it may occasionally do in both tuberculous and pyogenic meningitis, there may be need to exclude the presence of tuberculoma or brain abscess; for in the presence of a space-occupying lesion intrathecal injections of antibiotics may so alter the intracranial pressure as to precipitate catastrophic herniations of the brain. Streptococcal meningitis seems to be particularly dangerous in this respect, since it often coexists with a brain abscess whose symptoms are masked by the presence of meningitis (Smith *et al.*, 1946b); these cases must be distinguished from those in which meningitis and ventriculitis are the terminal events following rupture of a brain abscess into the ventricle.

There are also the cases in which the association of running ears with meningitis arouses suspicion that the meningitis is secondary to a brain abscess. There is yet another group of cases in which rapidly growing gliomas alongside the ventricles or basal cisterns may produce pleocytosis of the C.S.F., drowsiness, headache, and vomiting, and so simulate tuberculous meningitis. Red herrings are strewn across the path of clinical diagnosis in meningitis no less than in other diseases. By clinical methods, given time, they can be recognized for what they are, but time is not to spare.

The doubts and difficulties can be promptly solved by tapping the lateral ventricles. If both ventricles yield abundant C.S.F. it is safe to assume that there is no space-occupying lesion in the cerebral hemispheres (ventricular estimation); if the result of ventricular tap is equivocal there should be no hesitation in injecting air for ventriculography. We have used this method on many occasions in cases of acute meningitis and suspected meningitis and can report nothing but good from its use. It does not seem to upset the patient or aggravate the meningitis, whether tuberculous or pneumococcal. If there is no evidence of a space-occupying lesion the appropriate antibiotic can be promptly given by lumbar or ventricular route. And if a brain abscess is revealed, prompt evacuation or removal of the abscess combined with intrathecal chemotherapy may be life-saving.

Burr-holes for ventricular studies may on occasions disclose some unsuspected condition in the subdural space. In one case of very severe pneumococcal leptomeningitis burr-holes for the introduction of penicillin into the ventricles disclosed free pus in the subdural space, which was thereupon treated by local instillations of penicillin through an indwelling rubber catheter (Cairns and Russell, 1946, Case 5). In another case, of an infant with pneumococcal meningitis who could not retain penicillin in her C.S.F. for more than a few hours after lumbar injection of the usual amounts and thus could not get rid of her meningitis, burr-holes revealed a large subdural hydroma into which the subarachnoid penicillin was shown to be leaking (Smith *et al.*, 1946a, Case 8). After the subdural hydroma had been drained the arachnoid leak evidently closed, for the patient regained the power of retaining penicillin in her subarachnoid space and then her pneumococcal meningitis promptly subsided.

It was from this case that we learned that there is no barrier to the passage of penicillin from blood stream to subdural space, or in the reverse direction, as there is

between blood stream and C.S.F. The dura and subdural space behave like somatic tissues. This fact has since been repeatedly confirmed by studying the transmission of penicillin from the blood stream to subdural haematoma (Schiller *et al.*, 1948).

The cases which I have cited in this section are uncommon ones, and ventricular studies are not often needed in diagnosis of meningitis. But they may be required urgently in any case, and no hospital can regard itself as fully equipped to diagnose meningitis unless it has neurosurgical facilities readily available.

There is one further point: bacteriological diagnosis of the type of meningitis may sometimes be obtained from the ventricular fluid when repeated examination of the spinal fluid has failed. This applies especially in tuberculous meningitis, though in most forms of pyogenic meningitis also the organisms are abundant in the ventricular fluid.

Introduction of Antibiotics by Surgical Operation

(a) Into the Lateral Ventricles

In our first cases of pneumococcal meningitis to be treated with intrathecal penicillin, early in 1943, the ventricular route was used; but we soon found that penicillin injected into the lumbar subarachnoid space spread quickly into the ventricles "against the flow," and also into the cerebral subarachnoid space (Cairns *et al.*, 1944). Thereafter the lumbar route was used routinely, the ventricular route being reserved for those cases threatened with spinal block. The signs of impending block have already been described (Smith *et al.*, 1946a), and subsequent experience has strengthened our belief that, whenever there is suspicion that penicillin injected into the lumbar subarachnoid space is not spreading freely to all parts of the cerebrospinal pathways, frontal burr-holes should be made for tapping the anterior horns of the lateral ventricles. When the earlier impure preparations of penicillin were injected into the lateral ventricles they occasionally produced a reaction, but nothing of importance seems to attend the injection of the crystalline preparations in the usual dose (for adults, 10,000–20,000 units).

The cisternal route can be equally effective in cases of spinal block, but when there is severe head retraction or restlessness it may be difficult or dangerous; and we have observed a greater liability to severe reaction to antibiotics—stupor, pin-point pupils, incontinence of faeces—from cisternal than from ventricular injection.

In tuberculous meningitis the ventricular route for streptomycin has proved of great value in a small proportion of the cases, particularly in those in which the daily lumbar puncture becomes difficult. For a variety of reasons, which have been described elsewhere (Cairns and Taylor, 1949), we believe that, though they may not prove necessary, it is nevertheless an advantage to make frontal burr-holes at the beginning of streptomycin treatment in all cases of tuberculous meningitis.

These burr-holes are useful for other purposes than diagnosis and therapy: by ventricular estimation, supplemented at a later date by ventriculography, something can be learnt of the condition of the lateral ventricles in meningitis. At the beginning of pneumococcal meningitis the ventricles are smaller than normal, but within a few days they become slightly larger than normal. In tuberculous meningitis the ventricles are usually already dilated by the time there are signs of meningitis—a fact which suggests that the initial stages of this disease are relatively symptomless.

We learn from ventricular studies that there is always some progressive dilatation of the ventricles in meningitis, even in cases which show little or no sign of obstruction and no appreciable sign of brain damage.

(b) Into the Chiasmal and Adjacent Cisterns

In tuberculous meningitis the main deposit of granulation tissue is found at necropsy in the interpeduncular space, cisterna ambiens, cisterna chiasmaticus, and the adjacent sylvian fissures. These spaces are continuous with one another, and obstruction of the cisterna ambiens by fibrin or granulation tissue is likely to interfere with the spread of streptomycin, whether administered by the ventricular or by the lumbar route, to the more rostrally placed cisterns and to the sulci of the cerebral hemispheres. Therefore we have tried the effect of administering streptomycin direct into the chiasmal cistern through indwelling polythene tubes. Under local analgesia a small frontal flap is turned and the chiasmal region is exposed by lifting up the frontal lobe, and tubes are passed into the interpeduncular space and towards each sylvian fissure. Streptomycin solution (500 to 1,000 μ g. per ml.) is instilled through the tubes two to four times daily in amounts up to 6 ml. at a time for 10 days. Streptomycin levels in the fluid from the tubes at the end of six hours have usually ranged from 20 to 40 μ g. per ml.

We have used this method in seven patients, all but one of whom were infants or children. In one other case the tubes were inserted into the cisterna ambiens through subtemporal approach, but very little fluid could be obtained from that cistern and the method seemed inferior to the chiasmal approach. Of the eight patients three had excellent recoveries and five died. In four of the patients including one who recovered, the cisterns were already filled with organizing granulation tissue, and the tubes were probably of little use. The two best cases were those of an infant aged 20 months with intense infection and many positive films and cultures, and a boy of 9 years, both operated on about the eleventh day of symptoms, which was earlier than the others. In both cases abundant fluid escaped from the tubes in the intervals between streptomycin instillations.

The protein and cell content of the fluid from the interpeduncular region was always high, and in all except one case, in which there was a complicating spinal pachy meningitis, it was higher than that of the lumbar and ventricular fluids. For example, in one case, that of a infant of 8 months operated on on the fifteenth day of illness, samples of fluid obtained almost simultaneously showed:

	Protein (mg. per 100 ml.)	White Cells (per c.mm.)	Mycobacterium tuberculosis
Ventricular	40	62	—
Lumbar	130	98	++
Interpeduncular ..	1,000	175	++

It seems reasonable to conclude that from an early stage the most intense disease is in the interpeduncular and adjacent cisterns.

I have no evidence as yet that this method of administering streptomycin improves the recovery rate. If the cisterns are already solid with fibrin and granulation tissue it cannot be effective. On the other hand, if the cisterns are patent, streptomycin administered by the lumbar or ventricular routes should reach all parts and therefore there should be no need for interpeduncular application. Yet, since the protein content of the C.S.F. in the interpeduncular region is so high, continuous drainage of the fluid from that region for some days might be advantageous. This remains to be proved. From the experience to date we are satisfied that the method can be carried out without harm even in young infants who are seriously ill.

(c) Into the Subdural Space

In purulent pachymeningitis there is free pus in the subdural space and the condition is usually due to streptococcal infection, rarely β -haemolytic forms, and is secondary to spreading osteomyelitis of the skull following pansinusitis. The leptomeninges are often not infected until the terminal stages. Sometimes, however, the condition may accompany or follow leptomeningitis. The clinical picture is a sharply defined one, now modified, though not usually to an unrecognizable extent, by penicillin (Schiller *et al.*, 1948; Cairns and Schiller, 1948). Before the introduction of penicillin we treated 18 patients with this disease, and all died. Since early in 1943 ten cases have been treated with penicillin by the systemic, subdural, intraventricular, and subarachnoid routes, and seven recovered. In view of the fact that penicillin passes freely from the blood stream to the subdural space, it should theoretically be possible to treat this condition by the intramuscular route alone. But so far in practice it has proved necessary to instil penicillin solution into the subdural space at frequent intervals for several days through an indwelling catheter. One of the advantages of this method may be to prevent the formation of loculated subdural abscess, which is a common and dangerous complication.

Obstruction of C.S.F. Pathways with Rise of Intracranial Pressure, and their Treatment

There are two varieties of obstruction to consider: (i) obstruction by inspissated pus or granulation tissue which arises while the infection is still active, and (ii) obstruction by fibrous adhesions which comes on after the infection has subsided, sometimes years later. In addition the effects of these obstructions may be intensified by herniations of brain tissue, which have already been described. In general, treatment of obstructions in the purulent stage of meningitis should be by intermittent or continuous drainage of C.S.F., open operations being reserved for the cases which have reached the stage of fibrous adhesions and clear C.S.F.

It will be convenient to consider the obstructions according to site, but first some general remarks must be made on the question of diagnosis. In a case of acute meningitis which is not progressing favourably frontal burr-holes should be made. The onset of obstruction should be suspected from changes in the pressure and content of the ventricular and lumbar fluids. If pressures are rising and the lumbar fluid is still abundant, it is probable that there is blockage at the cisterna ambiens. If the lumbar fluid is scanty the hydrocephalus may be due to obstruction at the foramina of the fourth ventricle. Further information can be obtained from observing the spread of antibiotics. For example, if the fourth ventricle is obstructed an antibiotic injected into the lateral ventricle cannot be detected in the spinal fluid two to six hours later; or the test may be applied in the reverse direction. To be sure, the patient will already be having the appropriate antibiotic before the test is required, but with forethought doses can usually be so spaced that a satisfactory test situation is provided. If not, then a different antibiotic can be used as the test substance: for example, penicillin in tuberculous meningitis (Smith and Daniel, 1947).

In infants ventricular punctures can be made through the anterior fontanelle, which also serves as a useful guide to the state of intracranial pressure. In children the degree of separation of the cranial sutures as shown by radiographs is a reliable guide to the onset and course of hydrocephalus.

The onset of ventriculitis is apparent from the rise of protein, and usually also of cells, in the ventricular fluid.

The site of obstruction can be determined precisely only by ventriculography or encephalography. With skill in its manipulation a relatively small amount of air will suffice. In meningitis that is chronic from the start air studies should usually be made at an early stage of the investigations.

1. Foramen of Monro

Dott (1927) has described a case of unilateral hydrocephalus following fibrous obstruction of one foramen of Monro in an infant, due to an inflammatory process of infective origin, though there was no previous history of meningitis. The obstruction was successfully relieved by making a hole in the septum lucidum so that all fluid from both ventricles drained away through the healthy foramen of Monro of the opposite side.

There is another variety of obstruction of the lateral ventricle which we have observed after penetrating wounds of the body of the lateral ventricle (Cairns, *et al.*, 1947) and which Dorothy Russell (1949) has seen after haemorrhage at birth. A septum forms between the roof and floor of the ventricle, closing off a part of the ventricle which contains choroid plexus, with the result that there is progressive hydrocephalus of that part of the ventricle. I know of no evidence that it may follow meningitis, but it is possible that it might do so. It is important to recognize this condition, since it is easily cured by removing the choroid plexus in the obstructed part of the ventricle.

2. Aqueduct of Sylvius

If a patient with purulent ventricular fluid begins to deteriorate, with rise of ventricular pressure and increase of the protein content of the ventricular fluid, the probability of obstruction of the aqueduct of Sylvius by a plug of inspissated pus is considerable. The outlook is bad in such cases, and I cannot lay claim to any success. The treatment which we advocate in such a case is drainage of the C.S.F. from the ventricles in the hope that the purulent obstruction of the aqueduct of Sylvius will resolve first, intermittent drainage by means of repeated ventricular taps; if that is not sufficient, as judged by the clinical condition of the patient and the ventricular pressure, then continuous ventricular drainage. Irrigation with Hartmann's solution (Sachs, 1942-3) might also be tried. I have heard it suggested that insufflation of air by the lumbar route might be attempted, to blow the plug of pus out of the aqueduct into the third ventricle, but this is probably more than most patients with this condition could stand.

Glass stricture of the aqueduct of Sylvius is not uncommon, but there is no evidence that it arises as a sequel of meningitis (Russell, 1949).

3. Foramina of Magendie and Luschka

Obstruction at the outlets of the fourth ventricle may arise as a sequel of acute infection, when it is usually meningococcal, or from chronic forms of bacterial infection, when the variety of infecting organism is often undetermined. The obstruction may take place during the purulent stage, from silting up of the foramina by inspissated pus and fibrin, or at a later stage, when the C.S.F. has already become clear, from organization of granulation tissue. The site of the obstruction can be determined by air injection.

It is easy to reopen the foramen of Magendie by open operation in these cases, but if possible the operation should be deferred until the C.S.F. has become clear, the patient being treated over the acute stage by means of intermittent or continuous ventricular drainage. Operation at the stage of fibrous or glial adhesions is attended by the risk of recrudescence of the infection, and thus it should be accompanied by active chemotherapy.

If for any reason it seems inadvisable or impossible to deal direct with an obstruction in the fourth ventricle or in the aqueduct of Sylvius, an alternative pathway for the C.S.F. can be provided by ventriculo-cisternostomy, a procedure introduced by Torkildsen (1947). A catheter or polythene tube is passed into the posterior horn of the lateral ventricle and its other end is led into the cisterna magna. It is left *in situ*. This operation usually gives excellent results.

4. Cisterna Ambiens

Obstructions at the cisterna ambiens cannot be removed surgically. Alternative pathways for the C.S.F. can be provided by various routes, of which probably the most satisfactory is an opening of the anterior wall of the third ventricle (third ventriculostomy) so that fluid escaping from the third ventricle passes into the sylvian fissures, thence over the convolutions of the cerebral hemispheres to be absorbed. This operation is sometimes successful, but may fail for a variety of reasons—closure of the ventricular opening, escape of the C.S.F. into the subdural instead of into the subarachnoid space, or because entry to the sylvian and other cerebral fissures is still obstructed as a result of the previous meningitis.

With obstruction at the cisterna ambiens there is a great collection of C.S.F. in the posterior fossa and spinal subarachnoid cisterns. In the purulent stage of the disease repeated lumbar punctures with withdrawal of large amounts of fluid may tide some patients over from the stage of complete obstruction until the cisterna ambiens partly reopens itself.

5. Spinal Block

Spinal block does not usually produce symptoms, and its importance is that it interferes with the intrathecal administration of antibiotics. I have already indicated the alternative measures for continuing intrathecal therapy.

Risks and Advantages of Operations

The operative methods now used in meningitis carry little risk. Cases requiring major operations are infrequent, and by far the most common procedure is the fashioning of burr-holes for access to the ventricles. In our experience intermittent drainage of the ventricles is preferable to continuous drainage, which carries with it the risk of secondary infection, now lessened by the use of antibiotics, and in infants the risk of cerebrospinal fistula once the drainage tube is withdrawn. The use of air to localize obstruction in the subacute and chronic cases is followed by the risk of reactionary rise of intracranial pressure, which must be guarded against by intermittent or continuous ventricular drainage for a few days, if the obstruction is not immediately dealt with surgically. Another risk is recrudescence of acute infection following operative relief of obstruction in chronic meningitis, but this can be countered by appropriate chemotherapy. For the rest the risks of surgical intervention in meningitis are very small.

In acute meningitis operative methods may be useful in preventing sedimentation of pus. In the unobstructed case withdrawal of C.S.F. from the ventricle, the lumbar region, or any other part of the cerebrospinal pathways and injection of antibiotic must increase considerably the circulation of the C.S.F. and its mixture with the antibiotic, especially if fluid is aspirated and reinjected several times. This effect may be the explanation of the puzzling fact that intrathecal streptomycin treatment is necessary in tuberculous meningitis although a theoretically adequate level of streptomycin in the C.S.F. can be obtained by systemic administration alone.

The extra movement and attention which patients with meningitis receive when they have ventricular burr-holes may well be good for them, particularly if they are inert and comatose. There is considerable evidence that gravity acts unfavourably on the course of meningitis. In fatal pneumococcal or other forms of pyogenic meningitis a mass of gelatinous material is often found in the posterior horns of the lateral ventricles containing pus cells and bacteria which must for the time being be impermeable to penicillin and hence a possible focus of relapse. In fatal tuberculous meningitis it is almost invariable to find that exudate is more intense upon the dorsal than on the ventral surface of the spinal cord. The reasonable explanation of these phenomena is that they are caused by gravity; and it may

well be that the deposition will be prevented by frequent movement of the patient, and that restlessness is, within limits, a good thing for a patient with meningitis. I have been struck with the excellence of the results in patients with pneumococcal meningitis who are violently restless in the acute stage of the disease. The nursing of inert patients should therefore include frequent changes of position.

Conclusion

I have tried to indicate the surgeon's approach to the subject, based on anatomy and morbid anatomy, without defining any particular province which shall be his and his alone. The techniques employed in treatment and the sense of urgency which is required in any particular case come easily to the neurosurgeon by virtue of his training and his daily work, but they are not his exclusive province. The contribution which operative methods can at times make to the diagnosis and treatment of meningitis is considerable, but it must always remain subservient to the main problem, which is one of bacteriology and chemotherapy.

In a recent issue of the *Journal of the American Medical Association* (April 30, 1949, p. 1284) there is a description of the United States Navy's scheme to set up bone banks in some of its hospitals. It is considered that the plan, which has been made possible by the improved methods of freezing and preserving bone, will assist hospitals in which bone grafting is undertaken. Frozen human bone has been preserved for as long as 308 days in an ordinary ice-cream cabinet, and then used successfully in bone-graft operations.

AYERZA'S DISEASE, SILICOSIS, AND PULMONARY BILHARZIASIS

BY

Sir HENRY TIDY, K.B.E., M.D., F.R.C.P.

Consulting Physician, St. Thomas's Hospital

Ayerza's disease was first fully described in a monograph by Arrillaga, of Buenos Aires, in 1913. Arrillaga claims that it is a morbid entity with a fairly constant clinical course and picture terminating with cardiac failure and an extreme degree of cyanosis, the latter feature leading him to give it the name "cardíacos negros." The subjects are adults. The predominant pathological change is sclerosis of the pulmonary artery and its branches. The lungs also show chronic changes, a fact which brings the entity into the group of cardio-pulmonary diseases. The aetiology and the cause of the extreme cyanosis have been regarded as somewhat of a mystery. Syphilis was formerly thought to be the cause of the pulmonary arteritis, but this has been disproved.

Since the publication of this monograph a number of cases considered to be of a similar nature have been recorded under such titles as Ayerza's disease, pulmonary arteriosclerosis, and sclerosis of the pulmonary vessels. These cases form a motley group. They come from various parts of the world in small numbers, often single examples. The subjects are of all ages, many in very early life. In a few instances the aetiology is obvious—such as those cases with congenital cardiac lesions. An occasional case is claimed to be syphilitic. Many are ascribed to the end-results of chronic lesions of the lung parenchyma, thus belonging to the cardio-pulmonary group. When advanced cor pulmonale has developed and the heart fails there is inevitably cyanosis, but only in a few instances has it approached the extreme degree described by Arrillaga.

This heterogeneous collection of cases of varying aetiology and manifestations clearly cannot explain the frequency and the consistent features of the disease described in Brazil. What, then, is the explanation of its presence in this geographical area?

Pulmonary Bilharziasis

In the course of the last twenty years studies by members of the Faculty of Medicine of Cairo have gradually uncovered manifestations of lesions of the pulmonary artery and its branches produced by the action of bilharzial ova. Modern progress started in 1928 with the description by Sorour (1932) of the pathology, and Azmy and Effat in 1932 gave the first clinical account of two cases diagnosed during life. These pioneer communications were followed by clinical records by Day (1937) and by a very full pathological study by Shaw and Ghareeb (1938).

Since that time progress has been rapid, with studies by Moussa (1942), Bedford *et al.* (1946), Khattab (1946), Kenawy (1947), Erfan (1948), and others. These communications are of great interest and may be referred to for full details.

The clinical symptoms and physical signs, the radiological appearances of the lung and cardiovascular system, and the course and progress have been pieced together and correlated with the morbid anatomy. It is now possible to diagnose the condition clinically and radiologically at a fairly early stage during life, and numerous cases are being recognized.

Briefly, the initial morbid process may be said to be obliterative endarteritis of the small branches of the pulmonary artery resulting from the action of ova which reach the site as emboli. With repeated reinfections the

process extends centrally. Finally, the main branches of the pulmonary artery may become dilated to aneurysmal proportions and cor pulmonale develops. The lung parenchyma, however, remains uninvolved or only slightly affected, and fibrosis is completely absent. So long, therefore, as the right ventricle, by hypertrophy, is able to force enough blood past the obstruction the lung tissue can oxygenate it satisfactorily. Hence cyanosis does not develop till the heart fails, and even at that stage cyanosis never reaches the degree described in cardiacos negros. The gross changes in the pulmonary artery and its branches led Shaw and Ghareeb to suggest the name of Egyptian Ayerza's disease for advanced cases. This has often been used, but the condition is now more generally known as cardio-pulmonary or pulmonary bilharziasis.

These cases prove that advanced disease of the pulmonary artery and its branches does not of itself produce cyanosis. The cases in Egypt also differ substantially from those in Brazil in the mildness or absence of pulmonary symptoms, though certain allergic manifestations such as asthma are now being studied.

Is Silicosis the Primary Factor?

Thus there are two geographical areas in which sclerosis of the pulmonary artery and branches occurs with considerable frequency but with certain differences in the clinical course. The Egyptian group proves that the special features of Ayerza's disease in Brazil cannot be ascribed solely to the changes in the pulmonary artery and its branches.

The Egyptian delta is a flat country lying little above sea-level and completely devoid of mines, and the subjects of pulmonary bilharziasis are nearly all farmers or from the families of farmers. The Brazilian subjects, on the other hand, are gold-miners working in valleys at an altitude of 14,000 feet (4,270 metres) in the Andes. The occupation suggests that silicosis may be the primary aetiological factor, while the tremendous altitude may account for the unusually high degree of cyanosis. Ayerza's disease thus can be reasonably explained as the result of silicosis occurring at great altitudes.

Dr. K. O. Courtney, of the Canal Zone Medical Service, who is familiar with the locality, states in a verbal communication that the cases with cardiac failure were formerly brought down to the plain by train. The railway rises to 16,000 feet (4,880 metres) before starting the descent, and deaths during the journey were not uncommon. Patients are now brought down by air. It is observed that on reaching the plain the cyanosis improves.

Pulmonary bilharziasis is unlikely to be the principal factor in Brazil in view of the long pulmonary course. *Bilharzia mansoni* is the only type present in Brazil, and ova of this variety cannot reach the lung until after the development of bilharzial cirrhosis of the liver, which is accompanied by splenomegaly, but it is possible that the condition of the liver and spleen respectively might have been erroneously ascribed to alcohol and malaria, both of which are mentioned by Arrillaga as aetiological factors. The existence of pulmonary bilharziasis, so far as I am aware, has not been reported in Brazil, though it must almost certainly occur there, and a case in Porto Rico was reported by Clark and Graeff (1935). The histology of pulmonary bilharziasis is so specific that it can be readily diagnosed when the possibility of its presence is once recognized. The differentiation of silicosis and pulmonary bilharziasis radiologically would certainly present difficulties and has not yet been studied, but there are several parts of the world where the two processes may coexist.

It is therefore suggested that Ayerza's disease as seen in Brazil is the result of silicosis occurring at high altitudes,

while the possibility of pulmonary bilharziasis as a main or contributory factor should also be borne in mind.

THE INCIDENCE OF CANCER OF THE UTERINE CERVIX

BY

R. G. MALIPHANT, M.D., M.R.C.P., F.R.C.S.
F.R.C.O.G.

Gynaecologist, Cardiff Royal Infirmary

(From the Department of Obstetrics and Gynaecology, Welsh National School of Medicine)

Although cancer of the uterine cervix when taken early is to a large extent curable, the proportion of cases coming to treatment at an early stage is so small that little impression is being made on its mortality rate. Not one case in ten reaches hospital with the disease confined to the uterus, and many come with such extensive lesions that only palliative treatment is possible. In spite of the efforts expended in educating the public on cancer, and the emphasis placed on the subject in our medical schools, much delay is still due to ignorance and neglect, but late diagnosis is also attributable in large measure to the insidious manner in which the disease develops. In cancer of the cervix there is no close correlation between the length of history and the extent of the disease, and more than half the women seen at Cardiff Royal Infirmary within three months of the first symptom are classified as having a stage 3 or stage 4 cancer (Maliphant, 1947).

Whereas early cervical cancer is usually symptomless, many cases are devoid of symptoms until they are far advanced, and this clinically mute phase is one of the main obstacles to early diagnosis. It is for this reason that in some countries, and notably in the U.S.A., women of cancer age are now being encouraged to undergo periodic gynaecological examination as the best and often the only means of ensuring prompt diagnosis. Cancer detection clinics have been established in most large centres, and the number of cases of cancer discovered in presumably well individuals has been so high that the representative character of the persons attending the clinics has been questioned (Jones and Cameron, 1947).

In the extensive literature on cancer of the cervix very little information is available on the number of living persons afflicted with the disease, and the purpose of this inquiry is to ascertain its incidence rate, together with the relative probabilities of the disease developing in the various age, civil state, and parity groups of the population. Such data would not only provide information on the number of new cases that would be expected in a particular group of women but may also have a practical bearing on problems relating to the aetiology and control of the disease.

Women who develop cancer of the cervix are measurably different from other women, and an attempt is first made to ascertain the degree to which the cancer hazard is affected

by such variants as age, marital status, and parity. Many reports have shown the distribution of such characteristics in women who develop or die of the disease, but they have rarely shown the distribution of the same characteristics in the community from which the cancer patients have been drawn. It is with this object in view that our patients have been examined against the background of the local population. At Cardiff Royal Infirmary 1,200 consecutive cases seen during the 25-year period 1922-46 have been analysed: 80% were residents of Glamorgan. As 1931 was close to the middle year of this observation period the 1931 Census figures were used in the main as the standard of comparison. The age, civil state, and child-bearing experiences of the community are then correlated with the tendency to develop cervical cancer.

Age

In this series 98.5% of the patients were married, and their ages ranged from 20 to 80 years. Their distribution by age is shown in Table I, together with that of married (widowed and divorced) women in Glamorgan at the 1931 Census.

TABLE I.—Distribution by Age

Age Group (Years)	Cancer of Cervix. C.R.I., 1922-46		Married Women of Glamorgan: 1931 Census		Estimated Relative Risk of Contracting the Disease (a) as % of (b) (c)
	No.	% (a)	No.	% (b)	
20-24	5	0.4	15,877	5.2	7
25-29	14	1.2	32,306	10.7	11
30-34	53	4.4	38,399	12.7	35
35-39	123	10.2	38,540	12.7	80
40-44	162	13.5	35,692	11.8	114
45-49	205	17.1	33,164	11.0	155
50-54	211	17.6	30,214	10.0	176
55-59	187	15.6	25,443	8.4	186
60-64	126	10.5	19,798	6.5	161
65-69	75	6.2	14,603	4.8	129
70+	39	3.5	18,509	6.2	56 ?
	1,200	100	302,485	100	

Although cancer of the cervix may be seen at extremes of age, it is predominantly a disease of middle life, and only 20% of the patients had reached the age of 60. A little less than one-third (30%) were under 45, a little over one-third (36%) were 55 or over, and the remaining one-third (34%) were in the decade 45-54 years. It is not so much the age of the individual as the senescence of the uterus which determines the occurrence of the disease, and if regard be paid to the number of women living at a given age it is observed that the cancer hazard continues to rise until the age of 60. The risk in the various age groups may be expressed by showing column (a) of Table I as a percentage of column (b). It is noted that the relative risk of the disease developing increases enormously from age groups 25-29 to 30-34, and at ages 35-39 it is more than twice as high as at ages 30-34. The rate of increased relative risk continues to rise until the peak is reached at ages 55-59. From this point it shows a steady decline, the rate becoming steeper and steeper in older women. Beyond the age of 70 this gradient is probably fictitious, as our series, in common with others compiled from hospital figures, is likely to be deficient in women over this age.

Lane-Clayton (1927) has drawn attention to the divergence between the age incidence of uterine cancer as shown by hospital figures and by mortality rates. The older the individual the less likely is she to attend hospital, but Mackenzie (1939) has shown that it is not until the age of 70 is reached that age as such acts as a serious deterrent to obtaining treatment. The inclusion of missing cases at ages of 70 and over in the above series would mean an adjustment throughout the entire percentage distribution, and

this in turn would reflect on the relative risks given in column (c), but it is unlikely that the main deductions would be falsified.

Civil State and Child-bearing

Of the cancer patients 18 (1.5%) were unmarried and non-parous. Two single women who had borne children were regarded as "married" for the purposes of this inquiry. At the 1931 Census 22% of Glamorgan women over 20 years were unmarried, and at ages 35-64 years—the time of life in which cervical cancer is most common—10% were unmarried. The low incidence of the disease in single women is probably attributable to the comparative infrequency of cervical infection in this group. That cervical cancer does occur in single women, and apparently in virgins, recalls the inherent tendency of some individuals to develop malignant disease in the absence of any recognizable extrinsic predisposition.

That the increased risk in married women is due solely to child-bearing has been disputed, and sexual intercourse has been indicated as a factor of some aetiological importance. Here an attempt has been made to measure the relative importance of these two factors—sexual intercourse and child-bearing—by comparing the relative risks of the cancer developing in single women, nulliparous married women, and parous married women. The proportions of the cancer patients falling into these three groups were known directly, but the numbers in the community were estimated in the following manner. In March, 1946, a Family Census was conducted by the Royal Commission on Population, and on request the secretary of the Commission supplied Dr. Greenwood Wilson, medical officer of health for the City of Cardiff, with a duplicate set of those Census cards which related to Cardiff women. From an analysis of these by age, social class, and number of live births the proportion of married women in Cardiff who were childless in 1946 was calculated. It was found to vary within the limits of 13 to 18%, according to age and social class, but the mean figure for those over 40 in all classes was precisely 15%. The 1931 Census returns for the County of Glamorgan showed 21,613 unmarried women and 182,851 married women of cancer age (35-64 years), and on the assumption that 15% of the married women were childless the proportions of single women, childless married women, and parous married women in the community were obtained (see Table II).

TABLE II.—Comparison of Civil State and Parity of Glamorgan Women of Cancer Age (35-64 years) (1931 Census), with 1,114 Women of Same Age Group with Cancer of Cervix

	Cancer of Cervix	Community	Estimated Relative Risk of Contracting the Disease (a) as % of (b)
	(a)	(b)	
Unmarried	15 (1.3%)	21,613 (10.5%)	12
Married nulliparous	45 (4.0%)	27,438 (13.4%)	30
Married parous	1,054 (94.7%)	155,423 (76.1%)	125
	1,114 (100%)	204,464 (100%)	

From this it may be seen that for women of 35-64 years (1) approximately 99% of the cancer patients were married, as compared with only 90% of the community; (2) of 60 nulliparous women in the cancer series only 25% were unmarried, the corresponding figure for all nulliparous women in the community being 44%; (3) 94.7% of the cancer patients, as compared with 76% of the women of the community, gave a history of one or more confinements; and (4) only 4% of the married women with cancer were childless, as compared with 13.4% of the women of the community. The figures showing the relative risks run by the three groups indicate that when a woman has reached

the age of 35 or more her risk of contracting cancer of the cervix is twice as great if she has been married, and ten times as great if she has also had children, than if she were single.

Repeated Child-bearing

As child-bearing is so closely correlated with cancer of the cervix some addition to the risk would be expected after each confinement, but previous studies have failed to establish any association between the number of pregnancies and the supervention of cancer (Lane-Clayton, 1927).

The average number of births (excluding abortions) among 1,182 married women with cervical cancer was 4.5, while the general average fertility of married women aged 40 and over in the community was 2.8 (Cardiff, 1946). But the deduction from this evidence that cancer of the cervix is related to large families could be challenged on three grounds:

1. The two series differ in point of time—the cancer series relating to a 25-year period, 1922-46, and the Family Census to the end-point of this period. During the interval covered by the cancer series there has been a decline in the average size of family, and the difference between the two means may reflect merely this decline in fertility.

2. The Family Census figures, which formed the only available standard of comparison as regards parity, relate to Cardiff women, whereas 80% of the cancer patients came from outside

TABLE III.—Average Number of Births per Married Woman. Three Groups of Patients with Cervical Cancer Compared with the Wives of Manual Workers in Cardiff generally (Family Census 1946)

Age Group	Family Census 1946		Women Suffering from Cancer of Uterine Cervix					
			Glamorgan Women				Cardiff Women Only	
			1922-36		1937-46		1933-46	
	No. of Women	Mean No. of Births	No. of Women	Mean No. of Births	No. of Women	Mean No. of Births	No. of Women	Mean No. of Births
20-29	699	0.93	6	2.0	9	1.8	3	1.6
30-39	1,135	1.83	88	3.1	83	3.0	29	2.83
40-49	1,082	2.55	170	4.7	206	3.7	91	3.7
50-59	959	3.0	163	5.4	210	4.3	84	4.4
60-69	698	3.5	91	7.15	118	4.4	38	4.5
70+	443	4.0	15	5.9	23	4.8	23	4.3
	5,016	2.4	533	5.0	649	4.0	268	4.0

the city boundaries, so the differences could be explained if it were shown that the average size of family was greater among women outside the boundaries, from which most of the patients were drawn.

3. The Family Census figures relate to all social classes, while the cancer cases were patients seen in hospital, so the larger families in the cancer series could be attributed to their belonging to the lower-income groups.

To meet the first two points a separate analysis is made, subdividing the cancer series into three parts: those seen before 1937, those seen during the period 1937-46, and a separate group relating to Cardiff women only (Table III). For each group the average number of births per woman was calculated, and a comparable standard is provided from the Family Census. To meet the social class objection the Family Census figures were formed into two groups: (a) the wives of professional men, salaried workers, and employers of labour (1,765); and (b) the wives of skilled and unskilled manual workers (5,016). This second group is considered to be a suitable standard of comparison for the hospital patient series.

It is to be observed that no difference in fertility is apparent between Cardiff women suffering from cervical cancer and those residing in other parts of Glamorgan. When the fertility of the more recent group of cancer patients is compared with that of the lower-income groups of the community it is noted that the average size of family is always slightly greater in women with cancer, and this is true whether women of the same age groups are compared or whether cancer patients are compared with Census figures applicable to women ten years older. The consistency of the excess in every age group obviates the need for any arithmetical tests of significance.

In Table IV the relative risk of incurring the disease is calculated in women of 40 and over according to parity. Women under 40 have been excluded from this table, as the community figures would be weighted by large numbers whose families would not be complete and in whom the hazard of cancer would be small. These figures indicate

TABLE IV.—Percentage Distribution by Number of Children for (a) Married Women Suffering from Cervical Cancer and (b) Wives of Manual Workers (Cardiff, 1946) Women of Completed Fertility Only, Aged 40 and Over

No. of Children	Cancer of Cervix Glamorgan, 1937-46 (a)	Family Census Cardiff, 1946 (b)	Estimated Relative Risk of Developing Cancer (a) as % of (b)
0	32 (5.1%)	464 (14.5%)	35
1	84 (13.5%)	549 (17.2%)	78
2	115 (18.5%)	596 (19.0%)	97
3	95 (15.2%)	463 (14.5%)	105
4	69 (11.1%)	342 (10.7%)	104
5	58 (9.3%)	228 (7.1%)	130
6 and over	171 (27.3%)	540 (17.0%)	160
	624 (100%)	3,182 (100%)	

that women with many children suffer from cervical cancer more frequently than do women with few children or only one child, and the relative risk increases slightly with each confinement, so that the woman who has had six or more children is exposed to a risk twice as great as the woman who has had only one child. They do not support the view that one childbirth is as effective a cause of cancer of the cervix as repeated labours.

It is generally acknowledged that cancer of the cervix also has social and racial distinctions, but these have not been explored in this survey. There can be little doubt that the disease is more common in the poor of any community (Stocks, 1947), and this is not attributable solely to increased child-bearing. As the social scale is descended there is a small increase in the number of children per family, but other factors are probably operative in the lower-income

groups, and more would seem to depend on bad environmental conditions and defective personal hygiene than on the bearing of larger families. It has also been claimed that habits and customs are responsible for the relative infrequency of the disease in women of the Hebrew race. If Jewesses were as susceptible as Gentiles to cervical cancer the local Jewish women might have been expected to contribute to the series under review, but not one of the 1,200 patients was Jewish. The relative immunity of Jewesses to cervical cancer is not clearly understood. It has been attributed to the observance of the Mosaic Code by married Jewesses, with its laws of separation and insistence on genital cleanliness, and it has also been ascribed to the practice of ritual circumcision, but the view that it is a fundamental racial character acquired through inheritance is perhaps still the most acceptable.

Estimated Incidence

The incidence rate of the disease—the relative number of new cases occurring annually—may be determined on the basis of mortality or morbidity records, but mortality tables for cervical or uterine cancer are still difficult to interpret. Neither is it easy to obtain data directly concerning the number of living persons suffering from the disease. The number of women with cancer is larger than the number with diagnosed cancer, and still larger than the number seen at hospitals. In country districts relatively more persons with cancer fail to obtain hospital attention, and, in order to keep the number of such persons as small as possible, an estimate is best made in an area with good hospital facilities, reasonably accessible to all groups of the community.

Cardiff, with its relatively compact population, seemed to lend itself to this form of inquiry. Its sick and infirm are received by three large hospitals, and from their combined records it was found that during the 12-year period 1935-46 the mean annual number of new cases of cancer of the cervix diagnosed in Cardiff women was 22. This figure required adjustment to allow for the few cases which may have been treated elsewhere, and also for those who may have died at home, untreated or undiagnosed. With these adjustments, it was computed that 30 new cases of the disease develop each year in the women of Cardiff. As no evidence was found that patients coming to the Infirmary from outside Cardiff made the series less representative of cancer of the cervix cases in Cardiff, the distribution by age, marital status, and fertility of these 30 women is assumed to correspond with that of the main series as shown in Tables I and II. Relating the distribution so obtained to the population as recorded in the 1939 Register, the cancer hazard in women of ages 35 to 64 years, according to civil state and parity, is shown in Table V.

TABLE V.—Estimated Risk of Cancer of the Cervix Developing at Ages 35-64 Years for Single and Married, and for Parous and Non-parous, Women

Civil State and Parity	Cardiff C.B. Population, 1939 Register	Estimated No. of New Cases of Cervical Cancer per Annum		Estimated Annual Risk of the Disease Developing at Ages 35-64 Years
		No.	% of Total	
Married women:				
Non-parous ..	7,294	1.128	4	1 in 6,500
Parous ..	41,333	26.705	94.7	1 in 1,500
Total married women	48,627	27.833	98.7	1 in 1,700
Single women ..	7,907	0.367	1.3	1 in 21,500
Total women ..	56,534	28.2	100	1 in 2,000

From the foregoing it would seem that the probability of the disease developing in any one year in women of this age group ranges from 1 in 1,500 in parous women to

1 in 21,000 in single women. In Table VI a more detailed examination of the risk in married women is made according to age, against the 1931 Census figures.

TABLE VI.—*Estimated Risk of Cancer of the Cervix Developing in Married Women at Increasing Years of Age*

Age	Cardiff C.B. Population, 1931 Census	Estimated No. of New Cases of Cervical Cancer per Annum	Estimated Annual Risk of the Disease Developing
20-29	8,131	0.48	1 in 17,000
30-34	7,147	1.32	5,400
35-39	7,022	3.06	2,300
40-44	5,522	4.05	1,360
45-49	6,113	5.13	1,190
50-54	5,690	5.28	1,080
55-59	4,724	4.68	1,000
60-64	3,932	3.15	1,250
65-69	3,117	1.86	1,700
70-74	2,103	0.75	2,800 ?
75-79	1,214	0.18	6,730 ?
80+	865	0.06	14,400 ?
		30.00	

It will be observed that the cancer hazard is maximal during the sixth decade, when it is of the order of 1 in 1,000. Attention has been drawn earlier to the probable deficiency of patients of 70 and over in this series. This may require some adjustment of the number of new cases—increasing the numbers at ages 70 and over, and lowering by a corresponding amount the numbers under 70. As a result the risk of the disease developing at 70 and over is probably greater than the figures in Table VI suggest, but it is unlikely that the small adjustments required at ages under 70 would materially affect the calculated risks.

Discussion

Although cancer of the cervix does occur in unmarried women, and apparently in virgins, it is predominantly a disease of married life, showing a predilection for women who have borne children. What influence child-bearing has on the cervix to render it especially susceptible to cancer is not known, but the operative factor, whether traumatic, infective, or hormonal, has to exert its action for many years before the specific effect is shown. In this series 157 of the cancer patients were confined on only one occasion, and a mean interval of 20 years elapsed before the malignancy was discovered.

In 11% cancer appeared within 10 years of parturition, in 17% the interval exceeded 30 years, and in the remaining 72% the interval between the confinement and the cancer ranged from 10 to 30 years. The length of this interval had no influence on the morbid anatomy of the lesion or on the clinical course of the disease (Maliphant, 1947). Neither did the nature of the confinement seem to be significant: 82% of the parous cancer patients had normal obstetric histories, with an average of over four unassisted deliveries per patient; 15% had at least one instrumental delivery; and in 3% one or more of the confinements were described as difficult. It is highly probable that figures of this order would be found in a control series of women not suffering from cancer, which would not lend support to the view that trauma itself is an important causative factor in cervical malignancy.

Although the severe tears which may accompany a difficult instrumental delivery do not seem to be any more likely to lead to cancer in later years than the small lacerations concomitant with natural birth, they both allow organisms easy access to the cervical tissues. Infection, by stimulating hyperplasia, heteroplasia, and heterotopia of the glandular epithelium, disturbs the epithelial equilibrium at the squamo-columnar junction, and the resulting erosion has been described as a battlefield on which two types of

epithelium are the contestants. Erosions are commonly inflammatory in origin, but similar epithelial changes may result from hormonal influences, and, once established, such areas of epithelial restlessness seem to be of paramount importance as forerunners of cancer. Nevertheless, the percentage of erosions which become cancerous is very small. It has been estimated that more than half the adult female population have infected cervixes, and for every woman with an infected cervix who develops cancer there would appear to be approximately a thousand who do not (Table V).

Chronic cervicitis is a precursor of cancer only if it exists in conjunction with some unknown factor of individual susceptibility. This may be some form of hereditary predisposition or be dependent upon some underlying metabolic or nutritional disturbance. In this connexion it is noteworthy that Ayre (1947) found evidence of excessive tissue oestrogens coupled with low thiamin excretion in women suffering from cancer of the cervix, and he suggests that the disease may prove to be the abnormal response of cervical epithelium to chronic infection when it exists in the presence of nutritional deficiency of thiamin and a consequent excess of the specific growth hormone, oestrin. In any event, chronic cervicitis may be regarded as only one of several aetiological factors, and, even if it were established that clearing up cervical infection would prevent cancer, to prevent one case it would be necessary to maintain in a healthy state the cervixes of about a thousand women. It is probable that the medical profession, by treating cervicitis, is daily making a small contribution to prophylaxis, but there can be little prospect of any appreciable reduction in the incidence of the disease by such measures.

The only immediate hope of reducing the persistently high mortality from cervical cancer is by discovering more cases at an early stage. There is room for further educational effort to persuade women to report symptoms and to see that every woman who reports suspicious symptoms is thoroughly investigated. Diagnosis at the earliest phase could be possible only by routine examination of the apparently healthy. The annual or semi-annual examination of parous women over 35—the age at which the prevalence of the disease shows a rapid rise—could not fail to lead to the discovery of many cancers still in their silent phase, but the practical difficulties in instituting such measures for the community are evident. On the basis of the incidence rate found in this inquiry, it would seem that even in the more vulnerable fraction of the community—parous women aged 35 to 64—only one cervical cancer would be found annually in every 1,500 women examined, although no doubt other lesions, both benign and malignant, of the exposed sites would also be discovered.

Considerable interest is being shown in the various smear techniques as developed by Papanicolaou and Traut (1943) for the diagnosis of malignant disease of the genital tract, and in their applicability to mass surveys. In suspect cases these cytological methods cannot displace biopsy, but they may make an important contribution to the control of cancer as a screening test for the detection of symptomless cancer in the community.

Summary

The distribution of certain characteristics in a series of 1,200 women suffering from cancer of the uterine cervix is compared with the distribution of the same characteristics in the community, and the differences are considered to measure the differences in the risk of incurring the disease.

Cancer of the cervix is a disease of middle life, but the risk of contracting the disease continues to rise until the age of 60.

Beyond this age the risk shows a steady decline: while the female population is decreasing, the incidence of cervical cancer is decreasing at a faster rate.

The cancer hazard is increased by marriage irrespective of child-bearing, but the disease shows a predilection for women who have borne one or more children. Its occurrence seems to be independent of the nature of the confinement, but each pregnancy adds slightly to the risk of cancer developing in later years. Whether the responsible agent associated with child-bearing is infective or hormonal, it takes an average period of 20 years to produce its effect.

In women of cancer age (35-64 years) the probability of the disease developing in any one year seems to range from 1 in 21,000 single women, through 1 in 6,500 in childless married women, to 1 in 1,500 in parous women.

There is little prospect of effecting any appreciable reduction in the incidence of the disease by prophylactic measures, and the pressing need is diagnosis at a stage when cure is not only possible but probable by existing therapeutic methods. The role of periodic health examinations in the detection of symptomless cervical cancer in the community is discussed.

I am indebted to Dr. Lewis-Faning, statistician to the Department of Preventive Medicine of the Welsh National School of Medicine, for invaluable advice on the statistical aspects of this paper. My thanks are also due to Dr. Greenwood Wilson and to his chief clerk, Mr. Brain, for analysing the Family Census returns; to Dr. D. G. Morgan for details of cancer admissions to Llandough and St. David's Hospitals; and to my colleagues in the department of obstetrics and gynaecology for access to their case records.

PSYCHIATRIC PATIENTS AND THE DISABLED PERSONS (EMPLOYMENT) ACT

BY

A. HARRIS, M.A., M.D., D.P.M.

Assistant Physician

AND

MARY A. LANE

Psychiatric Social Worker

The Bethlem Royal Hospital and the Maudsley Hospital

In December, 1946, a system of weekly conferences between us and the disablement rehabilitation officers of the Camberwell Labour Exchange was instituted at the Maudsley Hospital for all patients presenting problems in the finding and choice of work.

The patient was prepared for the conference by at least one preliminary interview with the psychiatric social worker in which the purpose of registration under the Disabled Persons (Employment) Act was explained and his aspirations in the field of possible employment discussed. At the subsequent conference, when the medical and social aspects of the patient's needs could be explained to the D.R.O., doctor and social worker were able to contribute suggestions which seemed indicated as the interview proceeded. This arrangement was of particular value, as the D.R.O. alone would not have been in a position to judge what concessions he should make to the patient's objections or hesitations. It was also useful for the hospital team to be able to modify the plans and recommendations for the patient when, as a result of listening to the

interview, it became apparent that the type of work suggested was not in fact suitable or readily available.

As a result of early experience in the working of the scheme a form was introduced for all in-patients in which sections were to be filled in by the doctor, the occupational therapist, and the remedial gymnast, the aim being to collect all possible information concerning the patient's employability. The information available for out-patients was necessarily much more scanty.

Results

A follow-up inquiry was made not less than six months after the conference, chiefly by means of a questionnaire filled up by the patients. This paper is based on an analysis of the patients dealt with in this way who were first seen by the D.R.O. before Dec. 31, 1947.

Table Showing Results of a Follow-up

Diagnosis	In Employment				Unemployed		Untraceable		Total
	Settled		Pre-carious		Men	Women	Men	Women

Of the men 31 had changed their occupations and 27 were doing the same type of work as they did before their breakdown; 23 of the former were well settled and eight were in precarious work, and 19 of the latter were well settled and eight precariously employed. There is no evidence, therefore, that change of occupation in itself has any particularly harmful or beneficial effect. Two reverted to their previous occupation after attempts had been made to settle them in something thought to be more suitable. Eight were well settled in work of a type inferior to that they had undertaken before their illness. Ten were tradesmen and artisans, seven clerical and shop workers, 12 outdoor agricultural workers, drivers, etc., 18 labourers and unskilled workers, four were in training, and seven were following miscellaneous occupations. There were eight

patients of subnormal intelligence: three of these were in settled employment, three were in precarious employment, and two were unemployed. Of the 25 unemployed men 12 had had no work since they had been seen at the conference, whereas 13 had had some. Thirteen had had two or more jobs, but five of these were now regarded as well settled, while only three were unemployed.

Of the 14 women unemployed nine had had some work and five no work at all. Of those in employment, of the six women with depression three had clerical jobs, two shop-assistant jobs, and one was in domestic service; of those with anxiety state three had clerical jobs and one was in domestic service; the three schizophrenics were working in clerical jobs; the patient with organic disease was working as a domestic servant; and the psychopath was undergoing training for clerical work. The results were worse than in the men perhaps because women are not subjected to the same degree of economic pressure and find a position of dependence more acceptable socially.

Discussion

The diagnosis of psychopathic personality seems to carry an unfavourable occupational prognosis, as one would expect considering the implications of erratic and antisocial behaviour that it usually conveys, but the numbers are too small for the results to be statistically valid.

Age appeared to have surprisingly little effect. Examination of the age-diagnosis distribution showed little relation between them, the diagnoses being scattered diffusely through the age groups.

The relative lack of success with those who had merely attended the out-patient department compared with the ex-in-patients is probably due more to the high proportion of mild chronic cases which they contain—the more acute cases of favourable prognosis usually being admitted to the wards—than to any other factor, although they undoubtedly receive on the average less attention than the in-patients and information about them is less complete.

Failure to carry out the recommendations of the hospital was usually due to circumstances beyond the patient's or the D.R.O.'s control, but it was occasionally due to the patient's change of mind. Housing shortage is one of the chief factors limiting mobility and consequently choice of work at the present time, and one finds in practice that many patients have in fact only one or two possibilities to consider. The results are strikingly better in the cases where the recommendations of the hospital were carried out, but caution must be exercised in interpreting these figures as showing what could be achieved if a greater choice of jobs were available. A defect of the patient, such as difficulty in the interview with a prospective employer, might prevent both the carrying out of the hospital's recommendations and the effective settlement of the patient anywhere.

The 17 patients who never succeeded in getting any work necessarily fell into the "recommendations not carried out" group, but a considerable proportion of them were unemployable by ordinary standards. The small group who did well in spite of rejecting the advice given to them—for example, the man who was told that he should take up training in agricultural work but found himself a clerical job, and the telephone engineer who was told that his job was too difficult for him but nevertheless persisted in it—form a useful corrective to dogmatic attitudes. Nevertheless the figures suggest that a widened range of choice would substantially increase the chances of successful settlement.

An occupational therapist's report was available on 55 patients; the proportion of these who were at work was slightly higher than for the whole group because of the

refusal of some of the most difficult patients to do occupational therapy. Nearly three-quarters of those who were given favourable reports were in settled employment and two-thirds of those who were given poor reports were totally unemployed. It seems that the opinion of the occupational therapist affords considerable help in assessing the patient's employability in ordinary life.

The previous work records were classed as good, fair, and poor according to the amount of unemployment, the length of time that jobs were held, and the degree of success attained; in some cases information was not adequate for classification. They were, of course, prognostically significant, but the comparatively high proportion of those with poor records who achieved settled jobs is noteworthy.

In view of the general impression of the value of personal contact it would appear worth while to compare the results in the group of patients who were dealt with at the Camberwell Exchange, and so by the D.R.O.s who had attended the hospital conference, with those who were settled by other exchanges. Of the 11 male Camberwell patients eight were in satisfactory employment, one had had some work, one had been totally unemployed, and one was untraceable. Of the seven female Camberwell patients four were in satisfactory employment, one had had some work, one had had none at all, and one was untraceable. These figures show a statistically significant superiority in the results of the Camberwell group, which suggests that where placement can be made by the D.R.O. who has been to the conference it is on the whole more successful.

The general impression is that success or failure in any one case depends on the complex interaction of a wide variety of factors—social attitudes, family circumstances, environmental accidents, and personality qualities inherent in the patient—so that the finding of a method of approach to resettlement in employment applicable to the group as a whole is likely to prove extremely difficult. Although the patients remain stubbornly individual in the problems which they present, they cannot, of course, avoid being affected by processes influencing the general level of employment in the country. As the demand for labour rises it becomes progressively easier for them to obtain and keep jobs, and the removal of brakes on mobility, such as the provision of adequate housing, would help them as well as the healthy workers. This is a preliminary inquiry aimed at defining the problems and not at discovering a solution for them; the results may prove of some interest to those planning larger undertakings.

Summary

A follow-up of 122 psychiatric patients placed on the Disabled Persons Register was made—73 were employed, 39 were unemployed, and 10 were untraceable. Of those in employment 51 appeared well settled in their jobs and 22 to be holding on to them precariously. Seventeen had had no work at all since being put on the register. Groups separated on the grounds of age, diagnosis, and civil state showed no significant differences, and even those patients of dull intelligence seemed as likely to keep a job as the brighter ones, although the numbers were so small that there might well be differences which a more extended inquiry would make evident. The previous work record and the occupational therapist's report while the patient was in hospital had prognostic value with regard to employment. It seems that the fullest advantage of the hospital conference method is obtained when the D.R.O. who attends the conference is the one responsible for the actual resettlement of the patient.

Our thanks are due to the D.R.O.s of Camberwell Exchange, who have co-operated with us enthusiastically and offered us every help and courtesy; and to Mr. Lubin, of the Psychological Department of the Institute of Psychiatry, for a statistical examination of our figures.

PHYTO-PHOTO-DERMATITIS

BY

H. E. BELLINGER, M.B., Ch.B.N.Z.

Wing Commander, R.A.F.

Phyto-photo-dermatitis is a bullous eruption appearing on parts of the body which have been in contact with certain plants and simultaneously exposed to sunlight some 48 hours previously. Until recently (Roxburgh, 1947) standard textbooks on skin diseases have paid little attention to this relatively common dermatitis. We owe the term phyto-photo-dermatitis to Klaber (1942). It is an adequate name which describes the aetiology of an eruption caused by a variety of plants. The term phyto-photo-dermatitis includes dermatitis bullosa striata pratensis (Oppenheim), Oppenheim's disease, meadow dermatitis, parsnip dermatitis, and berloque dermatitis.

The incident described below is recorded because of the large number of cases occurring within a few days, and because of a surprising lack of familiarity with the condition shown by many practitioners and the patients and their relatives.

The disease is by no means unknown to country folk. However, many inquiries made over the past eight years in Wiltshire, Somersetshire, Devonshire, and Lincolnshire revealed that none of the people with whom discussions have been held realized the true causes of the dermatitis. In the country, children running bare-legged through long grass in the summer months are quite often affected, but as the parents are familiar with the signs and symptoms the doctor is seldom consulted. It is not common for adults to be afflicted in such circumstances. Whether this can be attributed to the style of clothing or whether some degree of desensitization occurs during childhood has not been ascertained. Another point of interest is that it seems to be more prevalent in districts where heath-land and moors exist.

Oppenheim (1926) gave the first clear and detailed description of the condition, which had affected a number of his patients sunbathing on the grass in the Viennese suburb of Ottakring. Two years later he realized the significance of contact with plants in the production of dermatitis, when he thought that siliceous compounds in the plants might be the important factor (Oppenheim and Fessler, 1928). From this time various plants in many different countries have been incriminated. Although Philadelphia (1931) seemed to have recognized that sunlight might be a factor in the production of the dermatitis, it was not until Kitchevatz (1934a), in France, carried out experiments with ultra-violet rays that the dermatitis was known to be due to a photosensitization arising from contact with the juices of certain plants. He later (1936b) ingeniously utilized the advent of an eclipse of the sun to strengthen his arguments.

Botanical Aspects

As further cases are published it is possible that many more plants possessing photodynamic properties will be recorded, but the following list of those involved in phyto-photo-dermatitis may be of value. References are also given as an aid to more detailed study.

The wild parsnip, *Pastinaca sativa*, appears to have been the plant first, and most commonly, associated with photosensitivity (Stowers, 1897; Hartmann and Briel, 1927; Heye, 1929; Hirschberger and Fuchs, 1936; McKinlay, 1938; Jensen and Hansen, 1939; Klaber, 1942). Cultivated parsnips have been reported by Whittle, Hellier, and Lee (1946) as being responsible for the dermatitis in some instances. Other plants accused are yarrow or milfoil, *Achillea millefolium* (Philadelphia, 1928; Gans, 1929; Spillman and Weiss, 1931); angelica, *Angelica sylvestris* (Bogdanovitch *et al.*, 1935), buttercup, *Ranunculus bulbosus*, and mustard, *Sinapis arvensis* (Spillman and Weiss,

1931); bindweed, *Convolvulus arvensis* (Klaber, 1942); common rue, *Ruta graveolens* (Oppenheim, 1932); the allier fraxinella, *Dictamnus fraxinella* (Baronovsky, 1929), and gas plant, *D. albus* (Cummer and Dexter, 1937); cow-parsnip *Heracleum sphondylium*, and its cultivated relatives: *H. giganteum* (Straton, 1912) and *H. mantegazzianum* (Miesche and Burckhardt, 1937; Kuske, 1938); figs, *Ficus carica* (Straton 1912; Legge, 1921; Kitchevatz, 1934c; Behcet *et al.*, 1939; Klaber, 1942); meadow grass, not identified specifically (Oppenheim, 1926; Hartmann and Briel, 1927; Corsi, 1933; Corson 1935; Kitchevatz, 1936a); Persian or Tahitian lime (Sams 1941); agrimony, *Agrimonia eupatoria* (O'Donovan, 1942).

It will be noticed that, although a considerable number of species are involved, they belong to a few families only: Umbelliferae (wild parsnip, cultivated parsnip, cow-parsnip yarrow, angelica); Rutaceae (common rue, gas-plant, limes); Rosaceae (agrimony); Moraceae (figs); Ranunculaceae (buttercup); Cruciferae (mustard). The majority of these plants belong to the families Umbelliferae and Rutaceae.

Geographical Distribution

Phyto-photo-dermatitis has a wide geographical distribution. Following on Oppenheim's first communication in Austria in 1926, cases were soon reported from Germany and France. In the latter country Jacowski collected several cases from the airfield at Etampes and its neighbourhood. Five were French airmen who, between June 23 and 29 1935, sunbathed or walked bare-legged in the grass. Two further cases were children belonging to French Air Force families living on the same station, exposed to the sunlight and grass at the same time. A number of other people so exposed were not affected (Jausion and Jacowski, 1936b). Cases were also reported from Italy, Yugoslavia, Russia, Switzerland, Denmark, Spain, and the United States of America.

From the time of Stowers (1897) no cases were recorded in Great Britain until Straton (1912) reported a case in Wiltshire following contact with figs. Corsi (1933) described the typical skin eruption in a student who indulged in sunbathing after a swim near Tunbridge Wells. McKinlay (1938) described several similar cases from Salisbury Plain where, later, O'Donovan (1942) reported some dozen more. Until O'Donovan's cases occurred in the hot summer of 1940 no importance had been attached to the disease. Public interest at this time had been aroused to the danger of noxious war gases, and the appearance of blisters on the skins of unsuspecting people—Service and civilian—gave concern to the local public authorities, who at first had the impression that the victims had come into contact with mustard gas. At that time I attended eight cases amongst Army personnel who were doing airfield guard duties in the heart of the Plain. These soldiers were undergoing intensive field training, stripped to the waist in the hot sunshine. They had thus come into contact with patches of cow-parsnip, which they used for concealment and cover. Within forty-eight hours the affected men's chests and bellies were covered with the characteristic striate, criss-crossed weals and blisters. Whittle *et al.*, quoted above, have also mentioned some cases occurring in France in 1944 amongst A.T.S. girls peeling cultivated parsnips in bright sunshine. Klaber (1942) recorded two cases due to contact with wild parsnip in 1940, and another in 1941 in which bindweed appeared to be involved.

Biochemical and Biophysical Aspects

The nature of the photosensitizing substance in these plants which causes the dermatitis has not yet been fully elucidated. Kitchevatz (1936a) showed that it is not chlorophyll, but that alcoholic extracts from figs had this property. Jausion and Jacowski (1936b) suggested that sweating as well as exposure to strong sunlight was required before

erythema and vesiculation followed an application of watery extract of grass. Obvious sweating was not found to be essential in the experiments detailed below. Following the production of bullae some forty-eight hours after the application of the undiluted juices of rue, wild parsnip, and figs in bright sunlight, Kuske (1938) began to investigate the photodynamic properties of a group of ketonic compounds known as furo-cumarins. Chemically pure compounds were obtained from oil of bergamot to produce bergapten, 8-methoxypsoralen from masterwort (*Peucedanum ostruthium*), and fucosin from figs, while others have been isolated from a number of essential oils as well as from dill and parsley. All these substances when applied to the skin in sunlight produced bullae or erythema after forty-eight hours, followed by prolonged pigmentation. It would be interesting if these complex ketones could be isolated from all the plants producing phyto-photo dermatitis, but that is beyond the resources of most clinical workers in this field.

Jensen and Hansen (1939) have elucidated the biophysical aspects of the problem in a series of carefully conducted experiments. They showed that the active range of the solar spectrum required to produce the dermatitis lies between 320 and 366 millimicrons in the long-wavelength end of the ultra-violet section, with a less active band between 264 and 280 millimicrons. These findings probably account for the incidence of the disease at the height of summer, when these rays are able to penetrate the atmosphere, and also explain the failure of a number of workers to reproduce the photodynamic effects with ordinary artificial ultra-violet rays. Jensen and Hansen further demonstrated that irradiation of alcoholic extracts of wild parsnip did not render the extract active of itself. Individual susceptibility to the plant was found to be unlikely in that all the subjects tested gave similar results.

Present Series

The cases occurred at a Royal Air Force station in Lincolnshire during the summer of 1947. Two different squads, with forty airmen in each, were sent by their physical-training instructors on a twelve mile race—the first on July 15 and the second on the 16th. The first mile or two was across fields and then over an assault course thickly overgrown with wild parsley (*Anthriscus sylvestris*) and yarrow, while the remainder of the run was along roads where an occasional patch of cow-parsnip was found in an immature stage of growth. The race on both days was held in brilliant sunshine, and the airmen ran in short trousers, many without vests or stockings. On the morning of the 17th an airman who had taken part in the first run reported sick, complaining of intense irritation and weals on the legs the previous evening, some thirty-six hours after exposure. By the morning large blisters had developed. During the next two days twenty three more airmen were found to be suffering from the same symptoms with varying degrees of severity. At the same time four officers' children and seven children from the married airmen's quarters, some of whom had been reported as having contracted chicken-pox, were found to be suffering from minor degrees of phyto-photo-dermatitis. Subsequent inquiries from the parents elicited the information that three of these children had been diagnosed as suffering from varicella in the same month a year previously, and that the skin eruption was identical with that of the present outbreak.

The clinical features of this series of cases were a sudden onset of itching or burning in areas of the skin exposed to the plants and sunlight simultaneously twenty four to forty-eight hours previously. Within six hours of the onset long linear weals with a bordering zone of erythema appeared followed in a few hours by bullae. The bullae varied in size from dew drops to large wrinkled blisters 5 in. (12.5 cm) in diameter. The blisters were surrounded by an areola of bright red erythema 4 in. (12.5 cm) wide, merging imperceptibly into the surrounding skin. The smaller bullae tended to be strung along straight weals like necklaces on a cushion, while the larger ones were oval or linear in shape and 4 to 10 in. (10 to 25 cm)

long. The largest blister completely encircled the left lower leg, and had a length of 5 in. above the ankle and a depth of 3 in. (7.5 cm). Seven ounces (200 ml) of straw-coloured fluid were removed by aspiration. The same airman also had numerous weals and smaller blisters on both legs, extending half-way up the thighs, and on the chest and abdomen down to the waistline. A pattern of scarlet stripes and long blisters criss-crossing one another, or with a tendency for several adjacent ones to run in parallel lines, was the characteristic picture. The skin between the lesions and the parts not exposed appeared to be normal. There was no associated conjunctivitis or rhinorrhoea. Seven severe cases required treatment in hospital, but within ten days the largest blisters had healed. Minor cases did not seem to be troubled for more than two or three days. A deep-purple pigmentation remained at the site of the lesions for the several weeks it was possible to keep most of the victims under observation. Four cases still showed faint but easily discernible pigmentation, faded to a violet hue, six months later.

Patch-tests were carried out on two hospital patients and two unaffected volunteers. The flowers, leaves and stalks of wild parsley, yarrow, and cow-parsnip were applied to the arms, control areas were protected from sunlight by adhesive plaster and test areas were exposed to the sunlight. Only the wild parsley exposed to sunlight gave positive results to the flowers, leaves, and stalks in all four subjects. Erythema appeared in twenty four hours, followed by small vesicles in forty-eight to seventy two hours. The patches were left on for six hours, and the subjects under observation spent most of that time in bright sunlight. For the remainder of the time under observation they remained covered. The tests were repeated on four more volunteers in much the same manner, but the flowers, leaves and stalks were only rubbed on to the normal skin. All four gave much stronger positive results with wild parsley than did those in the previous test on exposure to sunlight. This time, in one person, cow-parsnip produced erythema in seventy-two hours followed in a few days by desquamation and faint residual pigmentation. Aqueous and alcoholic extracts of the same plants were then painted on the arms of four subjects, one arm exposed to sunlight and the other covered. All four again produced erythema followed by slight vesiculation with both extracts of the wild parsley but not with other plants. One of the volunteers on to whose skin the plants had been rubbed still after eight months, has pigmentation of the areas which gave positive results with wild parsley.

The results obtained from these patch tests seem to confirm the observation made in the field that wild parsley was the offending plant in this series of cases. It would also appear that the photo-sensitizing substance is present in alcoholic and watery extracts. Support is given to Jensen and Hansen's suggestion that phyto-photo-dermatitis is not due to individual susceptibility to the particular plants giving rise to it. The fact that yarrow and cow-parsnip, both of which have been found by other workers to possess photodynamic properties, did not produce any result, or in the latter case produced only a weak one, is difficult to explain. It suggests that the same species of plants may possess photodynamic properties in one location and not in another, or that they possess these properties at a certain stage of maturity or at different periods of the summer. Further work is required to solve these problems.

Differential Diagnosis and Treatment

Since the effects of noxious gas warfare have become more widely known phyto-photo-dermatitis has more than once given rise to the belief that the patients have come into contact with mustard gas. It is, however, easily distinguished by the absence of erythema in the axillae and groins, of conjunctivitis or of respiratory and other systemic symptoms. The blisters of phyto-photo-dermatitis, though sometimes very large, are wrinkled like the folds of a slack tent and not tense and dome shaped as with mustard gas.

Phyto-photo-dermatitis is sometimes confused with varicella especially when children have one or two small bullae on the hands and legs. The characteristic mixture of fresh lesions crusting and healing vesicles of varicella is absent while the distribution of phyto-photo-dermatitis is on the exposed parts only.

Treatment consisted of aseptic aspiration of the large blisters and the application of sedative lotions such as calamine or calamine and lead, which tend to dry up the lesions. Liniment of calamine or zinc cream is useful in the late stages to keep the skin soothed yet supple.

Summary

Thirty-six cases of phyto-photo-dermatitis are recorded. A further eight cases are noted.

Wild parsley (*Anthriscus sylvestris*) was found to be the plant responsible for the outbreak. This was confirmed by patch-tests.

The history, the geographical distribution, and the biochemical and biophysical factors of the disease are briefly discussed, along with the species of plants indicated as causing it.

Differential diagnosis and treatment are also mentioned.

I wish to thank the D.G.M.S., Royal Air Force, Air Marshal P. C. Livingston, for permission to publish this article. Special thanks are due to Senior Sister Miss V. M. Ashworth, A.R.R.C., and to Flying Officer A. J. Beale for their interest and help in the investigations.

Addendum.—Since this article was prepared for publication three more cases have occurred on the same Royal Air Force station. Three aircraft apprentices, lying with rolled-up shirt-sleeves on the grass watching athletics on May 19, 1948, in bright sunshine, developed typical vesicles on the forearms on May 21. Investigation has not been completed in these cases.

THE PROGNOSIS AND TREATMENT OF SPRUE IN INDIA

BY

K. D. KEELE, M.D., M.R.C.P.

Physician, Ashford Hospital, Staines, Middlesex

In a clinical survey of 600 cases of sprue during the last war it was noted that only 31% had reached complete remission of the disease before evacuation from India, and it was believed that the relapse rate in England was high. The object of this paper is to assess the prognosis and results of treatment in a further series of 62 cases treated by me in India in 1945-6 and followed up for a period of two years in England. Their fate may be representative of that of the 1,073 cases sent back to England between 1943 and 1946. The value of the methods of treatment used in these cases can now be judged in perspective: and since these cases are likely to be the last treated without folic acid they may provide a basis for assessing the results of folic acid or other treatment.

Scheme of Treatment

Cases were treated on admission by diet alone or by diet with parenteral liver and other substances, according to the severity of the symptoms of relapse. Whenever possible, cases were treated by diet alone (Group 1). If diet failed and symptoms of relapse persisted, the patient was given for a preliminary period an "investigation diet," from which such therapeutic substances as liver were omitted (Group 2). With this diet the effect of parenteral liver, nicotinic acid, and riboflavin was assessed, particular attention being paid to clinical features such as weight stools, and blood count, as well as to fat-balance, glucose tolerance, and, in 10 cases, nitrogen balance. Ten cases showed such severe signs of relapse that no preliminary control period was possible and parenteral therapy was begun immediately (Group 3).

This grouping demonstrated the value of dietetic treatment alone. Cases which responded satisfactorily were classified as mild sprue. Those which failed to respond to a trial of dietetic therapy, or were so ill on admission that it could not be considered, were given parenteral liver and classified as severe sprue. It was therefore justifiable to attribute any improvement that occurred in severe sprue as due to parenteral therapy and not to dietetic measure alone. At this stage various remedies were tried in order to obtain preliminary assessment of their potency and/or mode of action. It was intended to do further trials of apparently active substances alone under controlled conditions in an adequate number of cases, but this proved to be impracticable.

These observations form the basis of the brief remarks in this paper on the value of various therapeutic methods used. Further details may be found in the report on sprue submitted to G.H.Q. India (in press).

Criteria of Progress

(a) *Short Term*.—Response to treatment was indicated by the appearance of the signs of the remission phase of the disease. These have been described in detail in a previous paper, in which it was emphasized that, besides gain in weight and cessation of diarrhoea, transient glossitis, desquamation of the skin, and increased abdominal distension almost constantly appeared. Steatorrhoea and abdominal distension were the first signs to disappear before completion of the remission phase. Thus the criteria for complete remission were (1) restoration of weight to within 10 lb. (4.5 kg.) of normal, (2) stools normal in number, colour, and fat content, (3) absence of abdominal distension, (4) ability to maintain Nos. 1-3 on a normal diet.

(b) *Long Term (after 2 Years)*.—Details have been obtained from each patient after two years in England as to (1) complete remission since return from India, (2) loss of time from work with symptoms suggestive of sprue or any other disease, and (3) necessity for hospital treatment with relapse. In the first group remission may be considered complete, and in the second partial; in the third treatment has failed. I am indebted to patients, doctors, and hospitals for details of cases which I have been unable to examine myself.

Results of Dietetic Treatment

(a) *Short Term (3 Months)*.—Fifty-two patients were treated initially with diet alone, by means of the Napier high protein-low fat sprue diets 3, 4, and 5. (See Table, (a).) The fat content

Blood transfusion was successful in two cases in which response to liver therapy was not adequate. All these cases were treated for some six months before being evacuated from India. Of the 25 cases 10 were in complete remission, 13 in partial remission, and two failed to respond. All those in partial remission continued to have steatorrhoea and abdominal distension.

Long Term (2 Years).—During two years 14 have been in complete remission, one has had symptoms keeping him from work, and six have relapsed and received further treatment in hospital. Three cases have not been traced. Of the two evacuated in a state of relapse, one has been in complete remission since his return, and one has developed pulmonary tuberculosis, entering a sanatorium in June, 1947, where he has since died.

The following summarizes these results:

	Short Term (6 months)	Long Term (during 2 years)
Cases in complete remission	10 (40%)	14 (56%)
Cases in partial remission	13 (52%)	1 (4%)
Cases having relapse	2 (8%)	6 (24%)
Died of pulmonary tuberculosis	—	1
Cases untraced	—	3
Total	25	25

Of 62 cases of sprue, therefore, 43 (69.4%) have remained well for two years in England, and a further five (8%) have had mild gastro-intestinal symptoms. Ten (16.1%) cases have relapsed since leaving hospital in India. Nine of these relapsed on the ship during evacuation to England under conditions of crowding, excessive heat, and dietetic insult. Five have suffered further relapses during their second year in England.

Diet	Calories	C	P	F	Vit. A (I.U.)	Thiamine (mg.)	Riboflavin (mg.)	Nicotinic Acid (mg.)	Ascorbic Acid (mg.)	
3	1,513	159	118	45	14,000	1.2	6.0	18.3	31	(a) Diets used in routine treatment (include liver 4 oz. orally daily)
4	2,109	233	139	69	16,000	1.4	6.3	25.5	31	
5	2,584	308	149	84	17,000	1.6	6.3	26.9	43	
Investigation										(b) Investigation diets used in therapeutic trials
I	2,037	215	139	69	1,900	1.1	3.2	9.4	28	
II	2,620	290	149	96	3,500	1.3	3.2	10.8	40	

(a) Napier's Diets 3, 4, and 5, as used in the dietetic treatment

(b) Investigation Diets. These modified Napier Diets were used for patients on parenteral therapy.

was checked at intervals by analyses of milk, fish, and meat. Thirty-seven of the patients were evacuated to England after about three months' treatment, 23 of them in a state of complete remission and 14 in partial remission. The remaining 15 failed to respond to treatment. Of the 14 in partial remission six had persistent abdominal distension alone and four had steatorrhoea alone; the remainder had a combination of these and failed to regain weight. However, all were progressing well at the time of embarkation, a date not governed by medical considerations.

(b) *Long Term (2 Years)*.—During two years 29 cases have been in complete remission, four have periodically developed symptoms keeping them from work, and four more have relapsed and returned to hospital. It is noteworthy that the 15 which failed to respond in the first instance were treated with parenteral liver as severe cases. The following summarizes these results:

	Short Term (to 3 months)	Long Term (during 2 years)
Cases in complete remission	23 (44.2%)	29 (55.8%)
Cases in partial remission	14 (26.9%)	4 (7.7%)
Cases having relapse	15 (28.9%)	19 (36.5%)
Total cases	52	52

Results of Parenteral Therapy

Short Term (6 Months).—This group of 25 cases comprised those previously mentioned who had failed to respond to dietetic treatment (15 cases), and those too ill on admission to be treated by diet alone (10 cases). All these cases were given investigation diets similar to the Napier sprue diets (see Table, (b)), but without foods with possible therapeutic value, such as liver, bananas, and vitamin concentrates. They received liver over long periods, and some were given trials of injections of nicotinic acid and riboflavin for a short time.

Effective Factors in Treatment

Much of the confusion regarding the treatment of sprue can be avoided by appreciation of the cyclic evolution of the disease. The characteristics of the relapse and remission phases of the disease have been previously described and will not be further discussed, but, as an example, the recognition that a glossitis usually lasting 2-3 weeks occurs early in remission has obvious bearing on assessing the efficacy of a therapeutic substance. Liver therapy is dramatic, and may be life-saving when given in relapse, but has no detectable action when remission has developed. All therapeutic effects must therefore be assessed according to the point in the disease which has been reached at the time of treatment. A patient in relapse will always pass through remission at a variable rate before reaching complete symptomatic cure. The therapeutic factors briefly noted below will be assessed from this aspect.

Diet (Napier's sprue diets 1 to 5).—Of 52 cases treated by diet alone, 37 (71%) underwent remission, but only 23 (44%) completed this phase in three months. Further cases recovered later, however, and 29 (56%) have remained well for two years in England. The effective factors in the diet are difficult to assess. Fifteen cases which relapsed or failed to improve on diet were deprived of liver, bananas, and vitamin extracts for periods up to 12 days as a preliminary to liver therapy, without any deterioration in their condition in this time.

Protein.—In 10 cases undergoing remission during liver therapy a positive nitrogen balance was found by Dr. R. C. Clutton. In one of these a negative nitrogen balance had

been present during relapse, due to increased faecal nitrogen. In spite of dehydration, several cases in relapse exhibited low plasma proteins, which rose during remission. These facts may indicate the value of a high protein diet in both phases of the disease.

Fat.—During relapse, in cases where fat balance was possible, absorption of fat still remained in the region of 50%. There was no evidence of fat excretion during remission in two cases on a fat-free diet. Raising the fat intake from 69 g. to 96 g. daily, when justified by the clinical state, did not alter the percentage absorbed.

Carbohydrate.—A glucose-tolerance curve is doubtful evidence of carbohydrate absorption in a disease which may involve liver function. Such curves, however, have been flat in relapse and often remained so for at least the first two weeks of remission, later rising to normal. Two cases since returned to England have had glycosuria, and one, since recovered, has been treated for diabetes for some months. This case had typical flat glucose-tolerance curves in India.

Vitamins of the B Group.—Nicotinic acid (150 mg. daily) and riboflavin (5 mg. daily), added to parenteral liver, produced no change in fat absorption or the clinical state in five cases, which were static in early remission. An impression that yeast extract slightly accelerated the already slowly increasing fat absorption needs confirmation.

Salt.—In one case in severe relapse the effect of 10–15 g. of sodium chloride daily by mouth was tried for ten days. During this time fluid stools rose from three to nine a day, weight dropped from 88 to 86 lb. (39.9 to 39 kg.) (normal weight 156 lb. (70.8 kg.)), anorexia increased, weakness became extreme, and there was vomiting. The blood pressure rose from 100/70 to 105/75 mm. Hg. Serum sodium rose from 258 mg. per 100 ml. to 310 mg. per 100 ml., the plasma volume rising from 2.1 to 2.5 litres. This patient responded well to subsequent liver therapy. The serum sodium changes well illustrate how improvement may be found in one facet of the case in the presence of gross clinical deterioration.

Sulphaguanidine.—This drug, given as for bacillary dysentery, improved the diarrhoea of relapse in sprue, often within 24 hours. The danger of dehydration was thus rapidly overcome, an invaluable advantage during the period of four days needed for liver to take effect. Sulphaguanidine was only partially effective alone, and diarrhoea returned when it was stopped. It did not produce remission of symptoms and its usefulness lay solely in controlling diarrhoea until liver became effective.

Liver Therapy

Although it has been known for some 20 years that parenteral liver is effective in sprue, its mode of action has never been clear. It has been presumed to be analogous to its effect in pernicious anaemia. As the haemopoietic action of liver was found to be delayed in these cases an attempt was made to ascertain the reason for its undoubted efficacy. The liver preparation used was a crude extract of Indian manufacture, and a sample assayed in England was reported as equivalent to a standard proprietary preparation as regards haemopoietic activity. Dosage used was 10 ml daily for four days intramuscularly, followed in most cases by a further 4 ml daily for some weeks.

The effects of liver depend on the phase of the sprue cycle during which it is given. It is active and beneficial in relapse but affords little benefit, if any, to a patient in remission. This is confirmed in the present group of cases by the fact that 13 of 25 patients were still in partial remission after some six months' treatment, during which liver was given over long periods. The more marked the relapse syndrome the more effective was liver therapy: its action

was not proportional to the severity of the anaemia. The effects of liver and the times of their occurrence are shown in the Chart. There was a latent period of 3–4 days; then

DAYS	1	2	3	4	5	6	7	8	9	10	11	12	13	14	LATER CHANGES
APPETITE						IMPROVED	+								LARGE
GASTRIC HCL															INCREASED
ABDOMINAL DISTENSION															INCREASED
INTESTINAL PATTERN															MAXIMAL IN WEEKS
MARKER TRANSIT TIME															RESTORED WITHIN 6 WKS
WATER ABSORPTION															INCREASED
NITROGEN BALANCE															+
FAT ABSORPTION															SLOWLY INCREASED
CARBOHYDRATE ABSORPTION															IMPROVED BLOOD SUGAR CURVE
STOOLS { NUMBER															NORMAL
{ NATURE															SOLID AND PALE
WEIGHT INCREASE															STEADY
BLOOD COUNT															R.B.C. INCREASE
MENTAL IMPROVEMENT															
SKIN CHANGES															PALLOR → PLETHORA → NORMAL
PARENTERAL LIVER EXTRACT															10 ML

glossitis, if present, disappeared rapidly, whether *post* or *propter hoc* is not clear. Mental improvement was early and marked. Skin pallor changed to a warm flush and desquamation appeared at the end of about one week. The appetite improved, and became large. Gastric hydrochloric acid increased. Highly acid resting juice with hyperchlorhydric curves—never found in relapse—were common. Abdominal distension increased for 3–4 weeks. After six weeks' liver therapy the intestinal pattern reappeared on barium meal in one case in which it had been absent during relapse. In four other cases showing good response to liver it was also normal. Transit time of a marker through the gut was prolonged.

Stools, though pale, became normal in number and consistency within 3–7 days. This diminished loss of water in the stools coincided with the beginning of gain in weight. In one case nitrogen balance became positive within a week of starting liver therapy. Fat absorption, apart from initial improvement with the cessation of diarrhoea, increased only slightly. The part that liver played in this is doubtful. Blood sugar curves improved inconstantly after two weeks, but it seems doubtful if this can be attributed to increased carbohydrate absorption alone.

Haematological changes have been described in a previous paper. Reticulocytosis was slight (not above 3%), but the red cell count slowly rose over a period of weeks, with steady diminution in the mean corpuscular volume to normal. It was remarkable how the blood count and the weight of the patient approached normal values together. On two occasions liver failed to produce the effects described, which were, however, initiated by a subsequent blood transfusion.

Conclusions

In these cases the action of liver manifested itself on the gastro-intestinal tract from tongue to colon, producing evidence of increased absorption of water and water-soluble substances. No such marked effect was seen on fat absorption. Haemopoietic response was slow and unlike that produced in pernicious anaemia. The effect of liver was, in short, to reproduce with remarkable accuracy the syndrome of remission which occurred in the mild cases on diet alone. Such observations supply strong *prima facie* evidence of the action of an intestinal factor in the crude liver extract used. Should such action be due to folic acid, this substance will be shown to produce a comparable therapeutic action in cases of sprue in relapse.

Summary

The results of treatment are described in 62 cases of sprue in India, later followed for two years in England. Complete

remission following dietetic and/or parenteral liver therapy occurred in 69.4% of these cases and definite relapse in 16.1%, nearly all of whom first relapsed during transit to England.

A brief review of the effective factors of treatment is given and the action of parenteral liver therapy analysed.

Medical Memoranda

A Case of Thrombophlebitis Migrans

The following case report may be of interest because it draws attention to the association of thrombophlebitis migrans with neoplasm, and because of an unusual event simulating an arterial block which occurred late in the illness.

CASE REPORT

A married shorthand-typist aged 25 was admitted to the hospital on April 16, 1948, with a three-weeks history of pain in the right side of the chest, an irritating dry cough, and increasing dyspnoea. In the past she had had bronchitis.

On examination she was febrile—100° F. (37.8° C.)—and was found to have a right pleural effusion with displacement of the mediastinum to the left. There was no clubbing of the fingers or evident enlargement of glands. A blood count showed: haemoglobin, 14.2 g. (96%); white cells, 12,300 (polymorphs 77%, lymphocytes 15%). The erythrocyte sedimentation rate was 6 mm. in one hour. The sputum showed mixed organisms, and β haemolytic streptococci in culture. Tubercle bacilli were not seen. An x-ray film confirmed the presence of fluid but was otherwise unhelpful. Pleural tap produced clear fluid, mainly lymphocytic, with some endothelial cells and an occasional polymorph. Culture was sterile. A provisional diagnosis of tuberculous effusion was made.

Owing to increasing dyspnoea, fluid was withdrawn from the chest on April 26 and 29 and May 4, 7, 12, and 14, always from the right side, although the effusion was bilateral by May 14. The specimen taken that day contained a fair number of red cells and 15% of endothelial cells.

On April 22 the patient developed pain in the right calf, thrombosis of the saphenous and femoral veins becoming complete over the next four days. Then thrombosis was detected in the left calf, and two days later there was swelling of the right arm, with pain over the right side of the chest, and haemoptysis, followed the next day by thrombosis in the left antecubital fossa. In view of the migrating form of the thrombosis a neoplasm in the chest was considered likely, but could not be demonstrated.

During the next week there was considerable improvement in the swelling of the legs; but a week later thrombosis of the right external jugular veins occurred, and after another week thrombosis of the innominate vein with dilatation of the veins over the front and back of the upper part of the chest.

On May 18 she complained of pain in the right hand, which was found to be blue and cold from the lower third of the forearm. No arterial pulsation could be felt with certainty below the axilla. There were no objective sensory changes over the affected hand or wrist. An arterial block was diagnosed, but embolectomy was out of the question, and the patient died some seven hours later.

Necropsy.—The principal findings were: (1) Bilateral pleural effusions and pericardial effusion. (2) A primary growth 1 cm. in diameter with a necrotic centre was growing from a minor bronchus of the right middle lobe of the lung. It was anaplastic, being partly spheroidal and partly squamous. (3) Multiple small nodules of growth were found in the parietal pleura and in the visceral surface of the pericardium. (4) Metastases were also found in the liver, both suprarenals, the left ovary, the head of the left femur, the lower deep cervical, paratracheal, mediastinal, and para-aortic glands, and the lymphatics of the pericardium and myocardium. (5) The superficial veins of the thorax were thrombosed, as were the jugular, the innominate, the vena azygos, and the main branches of the pulmonary veins. There was a large ante-mortem thrombus protruding from the superior vena cava into the right auricle of the heart. (6) Ante-mortem thrombus was also found in the axillary, brachial, and antecubital veins on the left, and also for about 1 in. (2.5 cm.) in the left femoral vein beneath the inguinal ligament. (7) The left axillary-brachial-radial artery was patent throughout its entire length and there was no evidence of embolus in it. (8) There was a very

small patent foramen ovale. (The skull was not opened, and other veins were not observed).

DISCUSSION

Two points of minor interest are: the youth of the patient—she was only 25—and the silent onset and rapid dissemination of the growth; for, apart from a recent bronchitis, from which she had made a complete recovery with a clear x-ray picture, she had been well.

The likelihood of a bronchial carcinoma being the primary cause of the pleural effusion was suggested by the onset of thrombophlebitis migrans, and was of course confirmed at necropsy.

Finally there was the occurrence of what appeared to be an arterial block in the left brachial artery, as evidenced by a cold, blue, painful hand and wrist, with a vague line of demarcation and absent arterial pulsation. It was debated at the time whether the block was due to an embolus from the lung or through a patent foramen, or whether it was due to an extension of the infected process to the artery wall from the neighbouring thrombosed vein. However, at necropsy no obstruction to the artery was demonstrable, nor could anything be found to account for this terminal episode.

C. A. HINDS HOWELL, D.M., M.R.C.P.,
Physician, Ashford County Hospital.

Otitis Externa Granulosa

The presence of granulations within the external auditory meatus is usually regarded as indicative of chronic suppurative otitis media, and this disease is in fact the commonest cause of their formation. It seems less well known that such granulations may be found in the presence of an intact drumhead and normal middle ear.

Clark (1946) described a granulomatous type of purulent otitis externa which he had seen when in charge of a British Army E.N.T. centre in India. He reported "a sessile plaque attached to the outer surface of the drumhead itself, or small pedunculated masses arising from the meatal walls." Moffett (1943), also from India, described and illustrated cases of "granulating myringitis," but he emphasized that in this condition no diffuse external ear inflammation was present. He did, however, state that "granulations in the external auditory meatus associated with various types of otitis externa are by no means uncommon."

While Command otologist for Austria (and for part of the time for North Italy as well) over a 12-months period I observed 13 cases of otitis externa granulosa. During the same period I saw 118 cases of otitis externa *without* granulations and 82 cases of chronic otitis media. (Cases of chronic otitis media with otitis externa *secondary* to the middle-ear discharge have been recorded only under chronic otitis media. Cases of furunculosis occurring *without* a pre-existing otitis externa have been excluded. Cases of otitis externa confined to the pinna were often dealt with by the dermatologist and have also been excluded. The term "chronic otitis media" has been used comprehensively to include long-standing chronic suppurative otitis media and cases of "old dry perforations" that had become reinfected.)

Most of my cases, in all three groups, were seen during the hot weather, and an association with swimming generally seemed to be aetiologicaly significant. The cases with otitis externa granulosa were usually those in which the cutaneous inflammation was especially severe or neglected and in which there was a foul-smelling purulent discharge. Such a case was very likely to be diagnosed and treated as C.S.O.M. by the unwary.

The granulations in my cases were more often of the pedunculated type, arising from any part of the deep meatus and only in the minority of cases having attachment to the drumhead. Three of my 13 cases were associated with a meatal furuncle. No cases of Moffett's "granulating myringitis" were seen.

The differential diagnosis from chronic otitis media was made by cleaning with wool mops (using olive or arachis oil) and the gentle removal of granulations with aural crocodile forceps. One could then see (though perhaps not till the second or third treatment) an intact drumhead with normal landmarks. The externa cases responded to cleansing much quicker than cases

of chronic otitis media with granulations. Another point was that the odour of the pus in some cases early raised a suspicion that one was dealing with an entirely external otitis. Also the transmitted pulsation often seen on observing the pus coming from a middle ear is absent in a purely cutaneous suppuration. The presence of mucus in the discharge sometimes indicated that there was a middle-ear infection before the perforation could be seen.

A variety of C.S.O.M. that one must be very careful not to confuse with otitis externa granulosa is that with granulations protruding from an attic perforation or from a meatal fistula. One can diagnose the latter by noting that the discharge comes from a fistula or attic perforation on using Siegle's speculum. Gentle use of a probe will confirm this.

Much has been written on the subject of treatment of otitis externa, and I do not intend to enter into details. In my cases I became convinced that by far the most important thing was gentle but thorough daily cleansing of the meatus. But granulations, when present, were removed with crocodile forceps, and occasionally use was made of a silver nitrate bead fused on to a probe. This alone rapidly cured most cases.

NORMAN A. PUNT, F.R.C.S.Ed., D.L.O.,
Late Major, R.A.M.C.

NOTE—Since the submission of this paper Johnston (1948) has written an excellent article on ear conditions, including otitis externa granulosa

Pre-pubertal Gonococcal Peritonitis

Peritonitis and salpingitis are rare complications of gonorrhoeal infection in female children (Bidwell, 1904; Hamilton, 1910; Koplik, 1910; Fraser, 1923; McLachlan, 1947). Few case reports have been published (Comby, 1901; Dowd, 1902; Hunner and Harris, 1902; Bidwell, 1904; Carpenter, 1904; Welt-Kakels, 1904), and statistics regarding incidence are difficult to obtain, but most would agree with McLachlan (1948, personal communication) that there is peritoneal involvement in about 1%. The following is the report of a case in which unilateral tubal involvement following an untreated gonococcal vulvo-vaginitis of short duration simulated acute appendicitis so closely that laparotomy was indicated.

CASE REPORT

A girl aged 7 was brought to the casualty department by her mother on April 27, 1948, with the complaints of vulval soreness which had begun twenty-four hours previously, abdominal pain of twelve hours' duration, and dysuria for three days. The mother had noticed that the child had a vaginal discharge at the time of complaining of dysuria; vomiting had occurred twice shortly before being brought to hospital. The bowels had been acting regularly. The mother denied having any symptoms, and stated that her husband was also healthy.

On examination the child appeared toxic. The face was flushed, the tongue furred and dry. The temperature was 101.8° F. (38.8° C.) and pulse rate 140. On abdominal examination, limitation of respiratory movement affecting the lower abdomen was seen and general abdominal pain complained of, but on palpation the maximum tenderness and rigidity were localized in the right iliac fossa. Inspection in the lithotomy position revealed a red, oedematous vulva, purulent vulvo-vaginal discharge, and redness of the vagina and urethral meatus. A film of the discharge showed pus cells and scanty Gram negative intracellular diplococci morphologically indistinguishable from gonococci. Culture confirmed that this organism was *Neisseria gonorrhoeae*.

A diagnosis of acute peritonitis was made, but, as appendicitis could not be excluded because of the major localization of pain in the right iliac fossa and a rising pulse rate, further examination under general anaesthesia, and possible laparotomy, were advised.

Under nitrous-oxide-oxygen-ether anaesthesia no abnormality could be felt in the right iliac fossa. Examination of the cervix by means of a small Ferguson-type speculum showed marked injection of the vaginal portion but no obvious discharge from the cervical canal. This suggested appendicitis rather than the rarer gonococcal salpingitis as the cause of symptoms. The abdomen was therefore opened through a right paramedian incision. A small amount of turbid odourless free fluid was found in the pelvis. In the right

iliac fossa the caecum and small bowel showed some patches of exudate and congestion. The right Fallopian tube was thickened and distended with purulent material, which was leaking from the fibrinated extremity. Bacteriological examination of this exudate showed numerous pus cells and typical Gram-negative diplococci, but no growth was obtained on culture. The left tube and ovary were normal, as was the appendix, which was not removed. The wound was closed in layers without drainage after a suspension of penicillin solution (500,000 units in 10 ml. of normal saline) had been introduced into the peritoneal cavity.

Convalescence was uneventful after the institution of a course of penicillin-sulphamezathine therapy, the child being discharged on the fifteenth day with a well-healed wound and no genito-urinary symptoms. Repeated examinations during convalescence and subsequently have shown no clinical or bacteriological sign of relapse.

Both parents were examined for gonorrhoea, with negative results; the epidemiological aspects could not, however, be satisfactorily completed, as the child had been on holiday some distance from home and it was impossible to trace contacts. As no history of interference was elicited, the inference was "accidental infection."

COMMENT

In the published reports the reason most often given for laparotomy has been the difficulty of accurate differentiation between acute appendicitis and salpingitis. Bloch *et al.* (1938) state that since Hatfield's case in 1886, 56 cases had been reported up to 1938, and in 20 of these laparotomy was performed because of incorrect or uncertain diagnosis. Notes (1938) added 16 cases of his own, in none of which did he perform laparotomy. Weill-Hallé *et al.* (1940) reported a further case treated successfully with sulphapyridine. A comprehensive summary of the condition is provided by Norris (1913) and by Maguire (1944), who stress the difficulty of excluding appendicitis as the cause of peritoneal signs and symptoms. The latter adds two cases, and mentions another of interest in which appendicitis was misdiagnosed as gonococcal peritonitis, principally because of the presence of leucorrhoea, and treated conservatively for four days before the need for laparotomy became evident.

In the case reported by us the possibility of the symptoms being due to gonococcal salpingitis was fully realized. The history, the localization of the abdominal findings, and the lack of cervical discharge made it impossible to exclude appendicitis completely. A therapeutic test with penicillin was considered, but, with a rising pulse rate, the delay of even a few hours which would have been prejudicial in a case of acute appendicitis seemed a contraindication to conservative treatment.

Our thanks are due to Dr. A. E. W. McLachlan for much helpful advice and encouragement, and to Mr. P. H. R. Ghey for permission to publish details of the case.

The U.S. medicinal chemicals industry manufactured £50,420,000 worth of drugs and other medical products during 1947, according to a report just compiled by the Bureau of the Census of the U.S. Department of Commerce. This represents an increase of 860% over the output for 1939, when the last census was taken. This phenomenal growth is partly due to the discovery of penicillin and other antibiotics and the increased use of other medical products, such as vitamins. The average number of workers in the industry for 1947 was 9,414 as compared with 1,802 in 1939, wages were 12 times larger than in 1939, and the total expenditure for new plant and equipment during the year totalled £3,375,000.—B.U.P.

ESSAYS ON SOCIAL MEDICINE

Measurements of the Public Health. Essays on Social Medicine By F. A. E. Crew, M.D., D.Sc., Ph.D., F.R.C.P.E., F.R.S. (Pp. 243; 57 figures. 18s.) Edinburgh and London: Oliver and Boyd. 1948.

Professor Crew follows the excellent plan of taking as the text for his book the data published by the Registrar-General for Scotland. He reproduces the more important tables, comments on their contents, points out how the vital statistics differ from those of other countries, and discusses their social and biological implications. For instance, the figures of multiple births lead the author to explain the difference between identical and fraternal twins and triplets, and that leads on to the question of Nature *versus* nurture. The chapter on the sex ratio opens with statistics of the ratio at birth and in the post-natal population, and common-sense remarks on the immediate causes are followed by a lucid account of the sex-determining mechanism. This leads to a brief study of the inheritance of haemophilia, and the chapter ends with a discussion of the usefulness of sex. No doubt one travels a long way from mere figures—thus, the statistics of divorce lead to observations on the origin of the family—but for readers with no passion for sums (perhaps a majority of medical students) it is surely the right method. It will persuade many that dull arithmetic can be both a foundation for and a means of testing very interesting social theories. It was the method of that great pioneer, John Graunt.

It may be a little ungracious to criticize the detail of an interesting book, but, as actuaries are often amused by lay misunderstanding of that overworked phrase "the expectation of life," it is necessary to say that the lower half of p 15 is incorrect. The expectation of life at any age is not the "probable number of years" a person of that age may expect to live, and actuaries do not construct life tables for the primary purpose of computing expectations of life. The expectation of life at age x is the sum of the lengths of life of all who died older than x , divided by the number who reached age x ; that is, it is the arithmetic mean of the frequency distribution of lengths of life where x is the origin of measurement. If, and only if, the frequency distribution were symmetrical, mean and mode (the tallest ordinate of the frequency curve) would coincide. The distribution of ages at death is very skew, and at different ages the mode is greater or less than the mean. For instance, at age 30 (E.L. No 10, males) the expectation of life is 38.21; the mode of the curve of deaths is between age 74 and age 75, so the "probable" after-life time is somewhere between 44 and 45 years. But at age 75 the expectation is 6.43 years, and the "probable" after-life time is less than a year.

However, a reader will not come to this book to learn statistics, but to gratify curiosity as to what vital and medical statistics suggest to an inquiring mind, and his interest should be stimulated by it. On the whole, Professor Crew's outlook is optimistic—possibly over-optimistic. He does indeed warn the reader that great pestilences may arise again, but he has confidence in our defences. "The freedom from the epidemic diseases which the Scottish population now enjoys rests on the unremitting attention of the public health authorities and their medical staffs and upon the intelligent awareness of the general public concerning the nature of these diseases and the means that have been made available for their control." But there is always the possibility that "flu" may become influenza. Between 1848 and 1889 nobody in Great Britain bothered his head over influenza, and by 1914 the younger generation had forgotten or never knew the influenzas of 1890 and 1891. Young people now do not remember the autumn of 1918.

MAJOR GREENWOOD

THE STRUGGLE TO SURVIVE

Reproduction and Survival. By R. Christie Brown, F.R.C.S., F.R.C.O.G. (Pp. 108. 6s.) London: Edward Arnold. 1948.

The author believes that the statement that reproduction is a physiological and a healthy process requires amplification. Without wishing to stress the dangers of childbearing, he thinks it necessary at the present time, when the public is being taught

that childbirth is simple and safe and should be more or less painless, to call a halt and review Nature's purpose in reproduction: to ensure survival of the race. In doing so Nature has no care for the parent. Numerous examples are cited in support of this view, from the mites that eat their mothers during hatching to the salmon that, after spawning, rapidly ages and dies, and the drone which, after fertilizing the queen, falls back to the earth dead, leaving most of his entrails attached to his mate. Nature, besides being ruthless, is on the whole stupid, favouring the survival of the physically strong and eliminating the weak. Medicine has different values, however, and recognizes that the physically weak are often mentally superior and therefore worth preserving.

While generally supporting this view—that Nature needs watching—the author makes a curious exception. He assumes, probably correctly, that the embryo elaborates its own hormones and is therefore dependent on itself for its intra-uterine survival. Although he administers hormones in early pregnancy to prevent miscarriage, he would withhold endocrine therapy after the eighteenth week, when elaboration of hormones by the corpus luteum ceases and the foetus has to rely on its own resources. He advances the interesting view that the stronger and healthier the foetus the more abundant the hormones produced in the placenta, and in consequence the more the mother suffers during her pregnancy; and, on the contrary, the less she suffers in pregnancy the less effective are the foetal hormones. But as the mother is then less prepared for labour—the cervix less softened, the pelvic joints less relaxed, and the uterine contractions less efficient—she loses in labour what she gains in pregnancy.

In the final chapter the philosopher becomes again the practical obstetrician who gives wise advice on how Nature's attempts to eradicate those she considers least fitted to survive may be frustrated. The work will appeal to those who want something different from the ordinary textbook. To others who are not interested in the arguments and speculations of the earlier chapters the last three will more than justify the small expenditure necessary to give it a place on their bookshelves.

F. J. BROWNE.

ELEMENTARY ANAESTHESIA

Elementary Anaesthesia. By W. N. Kemp, M.D., C.M. (Pp. 289, 100 figures. 55.00 or 27s. 6d.) Baltimore: The Williams and Wilkins Company. London: Baillière, Tindall and Cox. 1948.

This book gives a good picture of the modern transatlantic practice of anaesthesia and analgesia. It opens with a brief historical résumé, which is followed by an account of the physiological and pharmacological background to anaesthesia, and a description of the signs of narcosis. Premedication and modern techniques with general and local agents are well described, although no mention is made of refrigeration beyond a passing reference to ethyl chloride sprays. Curare is discussed adequately, but it is unfortunate that both "standard" and "high potency" solutions are referred to in "Squibb units" and not in milligrams. It should surely be possible by now for international agreement to be reached on such an important matter as the standardization of curare solutions.

It is perhaps inevitable that many British readers will not agree with some of Dr. Kemp's conclusions. He has, for example, a low opinion of trichlorethylene—"the only indication for the use of this agent is the total absence of other less toxic and more reliable general anaesthetic drugs such as ether, chloroform, cyclopropane, etc." Under anaesthesia for thyroid surgery the somewhat startling statement is made: "With the advent of propyl thiouracil, thyroidectomy will soon be a rare operation." This does not appear to be the present view of such American authorities as the staff of the Lahey Clinic. Dr. Kemp is a staunch supporter of the existence of "status lymphaticus" and devotes a whole chapter to the subject, including an account of some original work. He regards the cause of the condition as a temporary hypofunction of the adrenal cortex in a child already handicapped by inadequate thyroid function, the latter due to insufficiency of dietary iodine.

The binding, printing, paper, and illustrations are all first class, but there are many typographical errors, particularly in

proper names. For example, a casual reading showed that Henry Hill Hickman, Humphry Davy, von Liebig, Fourneau, R. R. Macintosh, R. Machray, and Joseph Priestley are all misspelt. This is a pity, as it tends to convey an impression of slovenliness which the book does not deserve.

C. LANGTON HEWER.

ABDOMINAL HERNIA

The Surgery of Abdominal Hernia. By George B. Mair, M.D., F.R.F.P.S.G., F.R.C.S. (Ed.). (Pp. 408. 138 figures. £1 5s.) London: Edward Arnold. 1948.

We can recommend this book as a reasonable and well-documented consideration of present views on all types of abdominal hernia. The author is for the most part justifiably critical of many modern methods, but he shows considerable partiality for the method of repair by whole skin grafts—a method of which he was a pioneer in Britain. It is perhaps unwise to allow thirty pages in a small book to such a full description of a type of operation which yet has to prove its merit in the surgical world.

After a chapter of general observation we are instructed in the management of strangulated hernia, and then chapter by chapter the author describes the various types of hernia, including their complications and a full account of the best line of treatment. It is impossible in a short review to discuss the many debatable views expressed, but it is clear that he has made a conscientious and informed attempt to assess correctly the merits of the various operations. The author states (p. 20) that a cold abscess will not give an impulse on coughing. The reviewer well remembers every member of an intelligent Fellowship class diagnosing as a femoral hernia what was in reality a cold abscess simply because it gave a good impulse on coughing.

The book is of handy size, printed on good paper, well illustrated, and there is a good list of references at the end of each chapter. In the bibliography of diaphragmatic hernia we missed the most valuable contribution of Dunhill.

ZACHARY COPE.

BACTERIOLOGY

Zinsser's Textbook of Bacteriology. Ninth edition. Revised by David T. Smith, M.D., Donald S. Martin, M.D., Norman F. Conant, Ph.D., Joseph W. Beard, M.D., Grant Taylor, M.D., Henry I. Kohn, Ph.D., M.D., and Mary A. Poston, M.A. (Pp. 992. illustrated. \$10.) New York: Appleton-Century-Crofts, Inc. 1948.

This well-known textbook, first published in 1910, the work of Zinsser, together with Hiss and later Bayne-Jones, is now dedicated to its original authors and re-compiled by seven of the present staff of the Duke University School of Medicine. It has been extensively revised, and its illustration, lavish even by American standards, includes many beautiful photographs and much useful graphic and tabular matter, particularly with reference to the epidemiological and public health aspects of its subject. In scope and scale it is much more than an ordinary textbook, and the professional bacteriologist will find it a useful guide to the best current American practice. The section on fungi, often lacking or inadequate in other textbooks, is particularly full, and nearly a fifth of the whole book is devoted to rickettsiae and viruses. There is very little to criticize, but we may note that "reversed selective bacteriostasis" is a myth, that the pigment produced by *Bact. melaninogenicum* is not melanin, and that *B. subtilis*, as far as we know, has nothing to do with hay fever. There are very extensive lists of references and an appendix on methods: the table of contents occupies 30 pages and the index 40.

L. P. GARROD.

1. *Surgeon's Domain*, by Dr. Bertram M. Bernheim (pp. 217; 9s. 6d. Kingswood, Surrey: The World's Work (1913), Ltd.), is a frank and amusing commentary on American surgery as seen through the eyes of one who, as he admits himself, came in by the back door. Dr. Bernheim has been for many years attached to the Johns Hopkins Medical School, and gives personal reminiscences of many of its great men. His cheerfully tolerant attitude towards dichotomy, commercialized operating, and slipshod diagnosis may alarm some of his readers in Britain and embarrass some of his colleagues in America, but the narrative runs with a cheerful swing that cannot fail to interest the surgical reader.

BOOKS RECEIVED

[Review is not precluded by notice here of books recently received]

Text-Book of Ophthalmology. By Sir W. S. Duke-Elder, K.C.V.O., M.A., D.Sc., Ph.D., M.D., Ch.B., F.R.C.S. Vol. 4. (Pp. 1,154. 70s.) London: Henry Kimpton. 1949.

This volume is concerned with the neurology of vision and motor and optical anomalies.

Nutrition and Physical Fitness. By L. J. Bogert, Ph.D. 5th ed. (Pp. 610. 21s.) London: W. B. Saunders. 1949.

A non-technical work.

A Comprehensive Review of Dentistry. Edited by V. F. Trapozzano, D.D.S., F.A.D.P. (Pp. 661. 32s. 6d.) London: W. B. Saunders. 1949.

In catechism form, written for United States dental students.

Histopathology of Irradiation from External and Internal Sources. Edited by W. Bloom, M.D. (Pp. 808. 48s.) London: McGraw-Hill. 1948.

Report of three years' research under the direction of the Atomic Energy Commission.

Muscles: Testing and Function. By H. O. Kendall and F. P. Kendall. (Pp. 278. 41s.) London: Baillière, Tindall and Cox. 1949.

Illustrated descriptions of muscle-testing procedures and their functional significance of muscle weakness and contracture.

Diagnostische und Therapeutische Eingriffe des Internisten. By E. Regenbogen. (Pp. 262. M. 14.40.) Stuttgart: Georg Thieme. 1949.

Clinical methods for the house officer.

Foundations of Psychology. Edited by E. G. Boring and others. (Pp. 632. 24s.) London: Chapman and Hall. 1948.

An elementary textbook.

Lung Dust Lesions (Pneumoconiosis) versus Tuberculosis. By L. G. Cole, M.D., F.A.C.R. (Pp. 474. \$10.00.) New York: American Medical Films. 1948.

Differential diagnosis is emphasized.

Cirugía de las Parálisis Espásticas. By F. B. Mora. (Pp. 156. 65 cents.) Jose Janes. 1948.

Surgery of spastic paralysis.

L'Anesthésie au Cyclopropane. By Dr. Lavoine. (Pp. 126. N. price.) Paris: Vigot. 1949.

A short account of cyclopropane anaesthesia.

Hematology. By C. C. Sturgis, M.D. (Pp. 915. 63s.) Oxford: Blackwell. 1949.

A comprehensive work.

Atlas der Augenkrankheiten. By R. Thiel. 5th ed. (Pp. 224. M. 60.) Stuttgart: Georg Thieme. 1948.

An atlas of diseases of the eye.

Les Maladies de L'Appareil Cardio-Vasculaire et les Maladies du Sang. By J. Trabaud and J. R. Trabaud. Vol. 4. 2nd ed. (Pp. 216. No price.) Paris: Vigot. 1949.

A handbook of treatment.

Die Durchleuchtungstechnik der Thoraxorgane. By E. A. Zimme. (Pp. 119. 12.50 Swiss francs.) Basle: Benno Schwabe. 1949.

An account of the uses of fluoroscopy.

Dermatologische Kosmetik. By L. Kumer. (Pp. 192. Sch. 30.) Vienna: Wilhelm Maudrich. 1949.

A short book on dermatology, mainly concerned with treatment.

Society and the Criminal. By Sir Norwood East, M.D. F.R.C.P. (Pp. 315. 10s.) London: H.M.S.O. 1949.

Anaesthetics for Medical Students. By Gordon Ostlere, M.B. Chir., D.A. (Pp. 108. 7s. 6d.) London: J. and A. Churchill. 1949.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JUNE 4 1949

AN A3 NATION?

The physical measurements and state of health of recruits to the fighting Services have often been used as evidence of the general health of the nation. In fact, in both peace and war such figures are of very doubtful value. In peacetime—before 1939, that is—the recruits offering themselves were self-selected and certainly not a cross-section of the young male population. In addition, the standards set for their acceptance or rejection varied from time to time with the needs of the Services for men. During war the examinations are spread over a very much wider field, but many occupations are reserved and the men in them not called up. Once more this limitation of the men medically examined must seriously affect the picture and make it inapplicable to the male population as a whole. The best example of such bias was probably the famous "C3 nation" report¹ of the first world war, for this was based upon the medical boards' returns for 1918, when the men examined were the residue of repeated examinations and the physically fit had already been enlisted.

With the coming into force in 1939 of the Militia Training Act a much more hopeful prospect of obtaining satisfactory statistics at once became apparent. Under the regulations every male aged between 20 and 21 years of age was obliged to register for military training. Owing to the outbreak of the second world war the examination of the, roughly, 300,000 young men concerned was not completed, but some 90,000 had been through the medical boards, their priority being based merely upon date of birth. A few exempted or deferred trades—the most important of which would be farm workers—prevent this sample being strictly representative in the statistical sense, but it is certainly good enough to give a reliable picture of the young men of 1939. These data were therefore made available to the Medical Research Council by the Ministry of Labour and have been fully analysed by Dr. W. J. Martin,² working in the Council's Statistical Research Unit at the London School of Hygiene and Tropical Medicine.

Martin's report is certainly a sound corrective to the pessimism created by the "C3" report of 1920, and, indeed, is encouraging in that it is based upon data obtained so soon after the years of economic depression in the early nineteen thirties. Slightly over 81% of those examined were put in Grade I—men fully fit or with remediable and only minor disabilities. Nine per cent. fell in Grade II—men with poor eyesight, deformities of the feet, or other moderate defects—while 5.2% came into Grade III and 2.7% into Grade IV—men with marked disabilities or serious disease. (A proportion of these would, of course, have been absent from the examinations—in sanatoria and

hospitals—and consequently there is some understatement of the number in the final grade.) Subdivision of these figures shows a rather higher standard of fitness in the countryman as compared with the townsman, and it is interesting to note that this superiority is quite, indeed particularly, distinct in the measurements of eyesight. Thus men with a visual acuity of 6/6 or better in both eyes formed 73% of the total in the rural districts, 67.5% in the small towns, and only 62.5% in the large towns.

The average physical measurements of all these young men are expressed by a weight of 135.7 pounds (61.6 kg.), a height of 5 ft. 7.5 in. (1.69 metres), and a chest circumference of 35.6 in. (89 cm.). In these measurements, too, the country dweller holds some advantage, and migrants from their place of birth were on the average physically superior, though slightly, to the stay-at-homes. This difference may bear upon the level of local mortality and morbidity rates, the migrants being, as has been believed in the past, the more physically fit. It is this mobility of the population that perhaps accounts for the relatively small differences in physique displayed by Martin's detailed regional analyses. The maximum difference in the mean stature is only about one inch (2.5 cm.)—from a mean of 68.1 in. (1.70 metres) in the home counties to 67.0 in. (1.68 metres) in Lancashire. In weight the differences are rather larger but not really great, the highest averages being 138½ to 138¼ lb. (62.88–62.99 kg.) in the southern and home counties, and the lowest 132 lb. (59.93 kg.), again in Lancashire. Taking the three countries as a whole, there is surprisingly little difference between England, Wales, and Scotland.

These figures, though confined to males of a particular year of life, are on an unprecedented scale for this country, and should clearly form a very useful yardstick against which to measure progress or deterioration. It may be hoped, therefore, that further analyses will some time be made of the post-war generation of young men. The value of this field of observation has also been recently, perhaps unexpectedly, shown in quite another connexion. In the investigation by Drs. Alice Stewart and J. P. W. Hughes of tuberculosis in the boot and shoe trade, published in this *Journal* last week (p. 926), it was found that the physique of men called up in 1942–3 was rather lower in the shoe-makers than in other trades. Thus it seems that this occupation may to some extent attract men of subnormal physique—a fact which might well contribute to the excess of phthisis among them. Martin's pre-war figures will also be of interest to the worker in anthropology and to those who have the rather more prosaic, but very important, task of seeing that machines, benches, uniforms, etc., are made to fit the man.

SURGERY IN THE TREATMENT OF
MENINGITIS

The development of the different sulphonamides, penicillin, and streptomycin has been of such rapidity that it is difficult to appreciate the improvement in the prophylaxis and treatment of many types of infections which have followed their introduction. Improved prognosis has emphasized the importance of early diagnosis and stimulated investi-

¹ *Physical Examination of Men of Military Age by National Service Medical Boards, 1920*. London: H.M.S.O.

² *The Physique of Young Adult Males*. Med Res Coun Memo No. 20, 1949. London: H.M.S.O. Price 1s 3d.

gators to determine the most efficient methods of systemic and local chemotherapy. In infections of the meninges, formerly so often fatal, the alteration in prognosis has been remarkable. Further, the risks of meningeal infection following brain wounds, basal skull fractures, and the surgical therapy of brain abscesses, as well as in other intracranial operations, have been greatly reduced. In a University of London lecture published in the opening pages of this issue Sir Hugh Cairns discusses the pathology and treatment of meningitis in the light of the knowledge gained since the introduction of chemotherapy.

Apart altogether from the infection of the meninges, there arises in most cases a varying degree of obstruction to the circulation of the cerebrospinal fluid. This is important not only because it leads to an internal hydrocephalus but also because it may prevent antibiotics introduced into the meningeal spaces from being adequately distributed through them. While in the early stage of the inflammatory processes such obstruction will be due to pus and fibrin, organization of granulation tissue at a later stage may cause permanent obstruction by fibrous adhesions. Such a possibility must be borne in mind and treatment given if necessary, for death from hydrocephalus may occur in spite of successful sterilization of the meninges. Even minor degrees of obstruction to the flow of cerebrospinal fluid from the ventricles to the subarachnoid space may be associated with the formation of a pressure cone at the tentorial opening or the foramen magnum, with a consequent aggravation of the block. Cairns stresses the tendency for meningitis to recur. This may be due to the persistence of the infective process which gave rise to the meningitis. The importance of adequate therapy for the primary lesion—for example, a chronic otitic infection—is thus clear. But recrudescence of infection may be the result of the encapsulation of organisms by non-vascular fibrin, which protects them from antibiotics: therapy must continue until the fibrin is absorbed or organized into a fibrous tissue capsule for the contained organisms. Alteration of the patient's posture may prevent the gravitation of pus and fibrin into the posterior portions of the ventricles and subarachnoid space.

The operations which may be required during the course of meningitis include such diagnostic procedures as lumbar and ventricular puncture and pneumo-encephalography, as well as the introduction of antibiotics into the cerebrospinal-fluid spaces. While lumbar injection of the latter may suffice, evidence of a developing spinal block, obtained manometrically and by examination of the cerebrospinal fluid, indicates the need for cisternal or ventricular injections. Meningitis may often follow head injuries in which there is a fracture of the anterior cranial fossa, and in cases of cerebrospinal-fluid rhinorrhoea or of aerocele dural repair must be carried out early to prevent this complication. If these signs are absent, and if there is no clear radiological indication of the site of a fistula between the meninges and the nose or one of its accessory sinuses, the indications for prophylactic surgery are by no means clear.

Perhaps in due course the most important aim of surgery in the treatment of meningitis will be to overcome obstruc-

tions to the cerebrospinal-fluid circulation. In the acute stage of such obstruction drainage of the inflammatory exudate by lumbar or ventricular puncture will suffice, but in the stage of formation of fibrous adhesions more radical treatment will be required. The site of the obstruction must be accurately determined—pneumo-encephalography is useful for this purpose—and it is also important to differentiate between the cases of communicating and non-communicating hydrocephalus. In this connexion Cairns suggests that antibiotics may be used as trace substances to replace the better-known Dandy dye test.¹ It seems likely that the obstruction to the circulation of cerebrospinal fluid in many cases of meningitis will be in the subarachnoid space—even when the hydrocephalus is of the non-communicating type; and when an obstruction in the neighbourhood of the cisterna magna exists it is probable that other cisternae in the posterior cranial fossa and above it will frequently be stenosed. In such circumstances an opening into the fourth ventricle through the obliterated cisterna magna will do no more than bring the ventricle into continuity with the subdural space. The recent advances in the treatment of meningeal infection may thus lead to the extension of the pioneer work of Dandy in the treatment of internal hydrocephalus. Perhaps a reduction in the secretion of cerebrospinal fluid which Dandy and, later, Putnam and Scarff² have obtained in cases of communicating hydrocephalus by cauterizing the choroid plexus may provide a solution in some cases.

INDUSTRIAL REHABILITATION

Occupational health may be difficult to define, but those whose aim it is to promote it are concerned, in the words of the Council's useful report on "A Comprehensive Occupational Health Service,"³ with the study of individuals in relation to the physical and psychological demands of their occupations, and of work and the work environment in relation to their effects on health. Many industrial workers with some sort of disability mental or physical, suffer from ill-health rather than occupational ill-health. They have made the best of things; they work in a job where their limitations are recognized and their capabilities allowed full expression and they feel content. There are others—and in many cases their physical disabilities are slight—who find it impossible to get back to work after an illness or accident. The industrial rehabilitation service takes care of these and it can also help those who, because of some long standing condition, are gradually overcome by a sense of inadequacy to such an extent that they feel incompetent to continue working even if the physical disability may be no worse. This service is run by the Ministry of Labour which established a centre at Egham, Surrey, in 1943 and since August of last year has opened eleven others, including the one at Leicester described on another page.

The work is still in the experimental stage, but the results so far seem to justify its being continued and indeed expanded. Most of the cases admitted to the Leicester

¹ *Ann. Surg.*, 1918, 68, 569.

³ *British Medical Journal Supplement*, 1949, 1, 296.
² *British Medical Journal*, 1949, 1, 965.
³ *British Medical Journal Supplement*, 1946, 1, 187.

unit have some mild psychological disability. The unit finds that a considerable number of these have become neurotic since being given a certificate for "light work" by their doctors. In many factories light work is menial work, and workers are apt to become demoralized by having to do it for long. Unfortunately, the only alternative open to most of them is to stay at home, though some of the Leicester staff thought that this would be the lesser evil. The ideal would be to send all those who wish it to a local rehabilitation unit, facilities for which do not exist at present in most places. Though giving the temporarily disabled light work seems to help the production drive, it may well in the end hinder it by creating a large body of men who, having once slipped from their industrial niche, are unable to return to it.

The Government's policy of full employment is too limited in scope: it refers to men rather than to ability. Many industrial workers are vaguely discontented because their talents are not fully employed. The rehabilitation services can help to solve the problem, though the best solution may lie deeper—in modifying industrial methods, on which much investigation is being done by industrial psychologists. An important function of these units is assessing ability. They give the man a chance to show what sort of work he is best able to do, and this is an important factor in restoring his self-confidence. It is essential also for doctors to know something of conditions in the factories where their patients work, and they can gain useful information and help from employment exchanges and the Ministry of Labour's Disablement Rehabilitation Officers. The fruitful results of collaboration with these officers are recorded by Dr. Harris and Miss Lane at page 982.

Whether the Ministry of Labour ought to be in charge of rehabilitation is questionable. It has established these units under the Disabled Persons (Employment) Act, 1944. Meanwhile the Minister of Health is urging hospitals to increase their facilities for rehabilitation. Though both Ministries are in Whitehall it sometimes seems that technical advances in the last 100 years have done little to speed communication between them, and it is unlikely that each could run its own rehabilitation service without duplication, confusion, and waste. The Minister of Health has stated recently in a memorandum² to hospitals that "every practitioner should assume responsibility for seeing his patients through to the point where they can either resume their former employment or be passed to the Ministry of Labour's disablement resettlement officers for placing in some suitable alternative occupation." Yet many of these are precisely the patients that ought to go to industrial rehabilitation units. The report³ of the Association's Rehabilitation Committee in 1946 emphasizes that the medical services of industry should be part of a comprehensive health service administered by a single Government Department, and the Council in its report on a comprehensive occupational health service expressed its opinion that the Ministry of Health is the appropriate central authority to plan and supervise such a service. It would seem to be proper for industrial rehabilitation to be a part of that service and come under the Ministry of Health.

SECRETARY OF THE MEDICAL RESEARCH COUNCIL

Under the National Health Insurance Act of 1911 provision was made for a medical research fund, and in 1913 the Medical Research Committee was established to administer this fund. Walter Morley Fletcher was appointed the first secretary of the committee in 1914, and when the Ministry of Health was established in 1919 the responsibility for Government-aided medical research was placed in the hands of a committee of the Privy Council. In 1920 the Medical Research Committee was reconstituted as the Medical Research Council and incorporated by Royal Charter. The secretary of the M.R.C. is also secretary of the Committee of the Privy Council for Medical Research. The Medical Research Council itself is responsible for the election of the secretary. It consists of twelve members, nine of whom are chosen for their scientific and medical distinction; of the other three one must be a representative of the House of Lords and one of the House of Commons. This rule of election removes the risk of political influence and interference with the work of the M.R.C., and the fact that its secretary is also secretary of the Privy Council committee provides for direct contact between him and the Lord President of the Council, the Minister responsible to Parliament for the work of the M.R.C. These sound provisions were the result largely of the wise statesmanship of the late Sir Walter Fletcher.

Sir Edward Mellanby retires from his position as secretary of the Medical Research Council on Oct. 1 and will be succeeded in this onerous and responsible post by Professor H. P. Himsworth, now Director of the Medical Unit of University College Hospital. Edward Mellanby, the second secretary of the M.R.C., was appointed in 1934. At that time he occupied the Chair of Pharmacology at Sheffield and was honorary physician to Sheffield Infirmary and a member of the M.R.C. At the time of his appointment he had already had a distinguished career as a research worker, research that had been largely directed to nutritional problems. In 1918 he showed that rickets was due to the absence from the diet of a fat-soluble factor, which McCallum and his co-workers subsequently proved to be vitamin D. He found phytic acid was one of the factors responsible for the rachitogenic influence of cereals which he had demonstrated in 1922. Mellanby summarized in his Croonian lectures to the Royal Society in 1943 his work on the effect of vitamin A on the growth and shape of bones and so indirectly on the function of the central nervous system. In 1946 we had the privilege of publishing¹ his discovery of the ill effect of agenzized flour on dogs, observations subsequently confirmed by himself² and other workers. One outcome of this is that the food and drug administration in the U.S.A. has introduced legislation against the use of agene in the bleaching of flour. It is indeed remarkable that Sir Edward Mellanby, in spite of the heavy and growing administrative duties of the secretary of the M.R.C., has nevertheless during his period of office been able to make such important contributions to

² *Ibid.*, 1947, 2, 283.

³ *Ibid.*, 1948, 1, 942.

⁴ *Ibid.*, 1948, 1, 983.

research; and it is of interest to note that his distinguished wife, Lady Mellanby, has shared his interest in nutritional problems in her series of investigations into dental caries. The severest testing-time for the Medical Research Council came in the war of 1939-45, and under its secretary's enlightened guidance the Medical Research Council threw itself into solving the many problems of health and disease confronting this country during that period of storm and stress. The work done during this time was recorded in a special report of the Medical Research Council and summarized in these columns.³

Professor H. P. Himsworth, whose election as the new secretary of the M.R.C. will be widely welcomed by the medical profession, has a difficult but inspiring task in succeeding to such eminent predecessors in his office. His published work gives an impressive record of research into various aspects of diabetes, on which subject he gave the Goulstonian lectures of the Royal College of Physicians in 1939. Another subject to which Professor Himsworth has made important contributions is liver disease, and in a review in these columns⁴ of his monograph on this, published in 1947, it was stated: "The crucial moment in Professor Himsworth's researches was when he decided that the best way to begin studying T.N.T. poisoning in man was to feed T.N.T. to rats." His contribution on another of his themes—thiouracil in thyrotoxicosis—to the Annual Meeting of the B.M.A. at Cambridge last year was published in the *Journal* of July 10, 1948. His work made him ideally suited as President of the Section of Experimental Medicine of the Royal Society of Medicine. In greeting Professor Himsworth as his successor the medical profession will wish Sir Edward Mellanby years of success in the research work to which he will now be able to give much more of his time.

CANCER OF THE CERVIX

The study of the social factors associated with cancer of specific sites has provided clues which have made possible the prevention of whole groups of cases, as, for example, industrial cancers of the skin, and there is evidence to suggest that in a similar way the commoner cancers of the mouth, stomach, lung, and uterus may be discovered to be preventable. Elsewhere in this issue Dr. R. G. Maliphant reports on a series of 1,200 cases of cancer of the uterine cervix which he has studied in order to determine the relation of this condition to age, marriage, and child-bearing. The Registrar-General's mortality figures have shown that cancer of the uterus is commoner in married than in single women, and that under the age of 55 it is relatively rarely associated with infertility. It is unfortunate that these figures cannot be separated into cases of cancer of the cervix and cancer of the body of the uterus, but probably the differences would be even greater in the case of cancer of the cervix. Nor can it be determined from the Registrar-General's data whether marriage contributes to the production of cancer of the uterus in any way other than by predisposing to child-bearing. On such points a clinical inquiry can be of great value.

The possibility that marriage could be of importance in itself, apart from childbirth, has recently been stressed by

Kennaway.¹ He has collected statistics from many countries indicating that the incidence of cancer of the uterus in Jewesses is only about a third of that in other sections of the community—a low incidence which appears to be due entirely to the infrequency of cases of cancer of the cervix. Handley² believes that this is a consequence of the male practice of circumcision, and he cites the low incidence of the condition in the natives of Fiji, where the men are circumcised, in contrast to that in the Hindu immigrants. Kennaway, on the other hand, suggests that the Jewish practice of abstention from intercourse during the first half of the menstrual cycle is a more likely explanation. If either of these hypotheses are true (and there are some who maintain that they are unnecessary and that heredity is a sufficient explanation) it must be expected that marriage will contribute to the development of cancer of the cervix even in the absence of child-bearing.

According to Maliphant's findings marriage does so contribute. In his series of cases marriage more than doubled the risk, while child-bearing increased it tenfold; moreover, the greater the number of children the greater the risk became. To obtain these results he compared his series, collected over the years 1922-46, with the Family Census conducted by the Royal Commission on Population in 1946. This difference in time detracts from the confidence which can be placed in the results, particularly that of increased risk with each addition to the size of the family—a finding contrary to Lane-Claypon's³ experience. For though the marriage and infertility rates may not have altered appreciably, the average size of family has certainly fallen. Maliphant recognizes the difficulty and makes such allowances as can be made, but, good though his reasoning is, some doubt must remain until a more exactly controlled series can be obtained.

He does not believe his findings indicate that any prophylactic measures are practicable other than early diagnosis. Yet if marriage in itself increases the risk, and Jewish women, who do not notably refrain from marriage, are largely immune, it would seem reasonable to inquire whether there is not something that can be learnt from Jewish customs. There remains also the Registrar-General's observation that uterine cancer is commoner among women of the poorer social classes, single as well as married, and this observation may also suggest methods of prophylaxis.

PREGNANCY AND THE THYROID GLAND

The role of the thyroid gland in pregnancy, and the changes it undergoes, have been the subject of much speculation though but little careful investigation. Certain facts are undisputed: for example, complete absence or extirpation of the thyroid gland causes sterility in both sexes, though once pregnancy is established thyroidectomy does not interrupt it; clinical hyperthyroidism does not prevent conception or alter the normal course of pregnancy; and hyperplasia of the gland occurs in pregnancy, though there is no certainty that this hyperplasia is associated with hyperfunction. On the other hand, the evidence is much less conclusive for the widely held belief that hypothyroidism, even of "subclinical" degree, may cause impaired fertility and that administration of dried thyroid extract corrects the condition, or for the perhaps less generally accepted opinion that hypothyroidism may be responsible for abortion, toxæmia, and other disorders of pregnancy.

In order to gain more certain knowledge of some of these relationships Peters, Man, and Heinemann¹ studied

The precipitable iodine of the serum in several groups of women. They found that in normal non-pregnant women the precipitable iodine varies between 4 and γ per 100 ml. of serum. In 22 pregnant women, on the second month of gestation to full term, the range was from 6.2 to 11.2 γ (mean 8.3 γ). This rise in serum precipitable iodine was found not to run parallel with the rise in the basal metabolic rate, since the former occurs very early in pregnancy whereas the latter begins only after the fourth month. Twelve precipitable iodine estimations on the sera of women with threatened abortion, or who actually aborted, ranged from 2.8 to 5 γ per 100 ml.; in eight of these cases the figure was less than 6.2 γ , which was the lowest concentration found among normal pregnant women. None of these women showed signs of hypothyroidism. Seven patients in whom serum iodine concentrations of less than 6 γ per 100 ml. were discovered early in pregnancy were treated with thyroid extract; in all cases the treatment raised the level of precipitable iodine in the serum, and the pregnancies proceeded without interruption. With commendable caution the authors suggest that deficiency of precipitable iodine in the serum may be the cause of some, though certainly not all, miscarriages. They estimated the concentration of precipitable iodine in the serum of women with histories of repeated miscarriages in the intervals between pregnancies, but they found no significant differences when these figures were compared with those obtained in the case of normal non-pregnant women, or did they find the serum precipitable iodine below normal in any of a group of 20 women who sought advice because of infertility. The latter finding lends no support to the belief that thyroid deficiency is a frequent cause of infertility. In four cases of toxæmia of pregnancy the values were again within the normal limits for pregnancy.

It cannot be regarded as proved that the amount of precipitable iodine in the serum closely reflects the thyroid hormone content of the blood. However, there is evidence to support this contention, notably that provided by Taurag and Chaikoff,² who by means of the technique of isotope dilution—using thyroxine labelled with radioactive iodine—have directly identified the precipitable iodine of normal serum with thyroxine. Though the number of cases studied by Peters and his colleagues was small (as they fully admit), their investigation of the thyroid gland in pregnancy is a useful contribution to the subject. Since the technique of assaying the precipitable iodine in the serum is relatively simple, there should be no practical difficulties to prevent similar studies being undertaken on larger groups of cases.

TREATMENT OF ANGINA WITH THIOURACIL

The treatment of angina pectoris by total removal of the thyroid gland was introduced by Blumgart, Levine, and Berlin in 1933, and though it met with some success it has since been abandoned, even by its authors, owing to the serious and irrevocable nature of the operation, the difficulty of estimating the required dose of thyroid extract in patients with spontaneous variations in the severity of their angina, the raised blood cholesterol, and occasional unfortunate complications such as tetany and recurrent laryngeal paralysis. Nevertheless, the idea that angina pectoris could be improved by reducing the circulatory demands of the body and by depressing the physiological responses to adrenaline was sound. When thiouracil began to be used clinically it was an obvious step to try it in cases of angina pectoris, for if the result was unsatisfactory the drug could be abandoned and the *status quo* restored. The usual dose of 0.2 g. t.d.s. until there is demonstrable improvement,

when it may be reduced to 0.3–0.1 g. daily. With propylthiouracil toxic reactions are rare, but fever and rashes are not uncommon with methylthiouracil, which may not be well tolerated by patients with angina. The usual precautions against agranulocytosis must also be taken. Treatment should not be considered a failure unless there is no improvement after six weeks; most patients are better after 14 days.

Fisher and Zukerman¹ strongly support the claims made for thiouracil in the treatment of angina pectoris: they obtained good results in 14 out of 16 cases. Last year in this *Journal* Dr. G. Shoenewald² also reported good results in three cases. In a series of 10 cases Hollander and Mandelbaum³ noticed improvement in only four after treatment with propylthiouracil, but they consider further trial of the drug is warranted. It is time a large series of cases was treated under scientifically controlled conditions.

THE ROYAL SOCIETY

The guests of the Royal Society at its *Conversazione* on May 26 once again enjoyed an exhibition of intellectual grace and wit without having to endure the many hours of patient research that lay behind it. Several advances in microscopy of interest to medical men were demonstrated. Mr. J. Dyson, of the Associated Electrical Industries Research Laboratory, showed how a microscope could be adapted by means of a special optical system for examining material some distance from the objective lens. Surgeons may find such an instrument useful for scrutinizing more closely the tissues displayed at operation if sufficient illumination can be obtained. Phase-contrast microscopy, by which the structure of living unstained tissues and organisms can be clearly discerned, was a feature of last year's exhibition. On Thursday Dr. J. R. Baker and his colleagues, of the Department of Zoology, Oxford, showed how an ordinary microscope can be adapted to the method with simple apparatus and at low cost. Their ingenuity should be of help to medical schools, where all the microscopes could readily be used for routine teaching by the phase-contrast technique.

The National Institute of Medical Research was displaying beautiful electronic micrographs of viruses adsorbed on the membranes of fowl red cells, and in a quiet corner it illustrated with skiagrams and photographs the dire effects of rickets on *Xenopus laevis* toads. When *xenopus* toads were bred in this country after their importation had been prevented by the outbreak of war they were found to have bony deformities and fractures, characteristic features being enlargement of the lower jaw and arched back. Investigation showed that, unlike rats, they must be supplied with vitamin D as well as calcium and phosphorus for bone formation. Dr. Lester Smith, of Glaxo Laboratories, showed how the anti-pernicious-anaemia factor, vitamin B₁₂, is extracted by means of partition chromatography from liver, which contains only about one part per million.

A notable contribution to the amity of man was a machine that played noughts and crosses with a human opponent. The Fellows were to be seen battling bravely against its electrical circuits, but logic triumphed, and it always won or drew, though on one occasion a spirit of slightly embarrassed satisfaction ran through the audience when it made a mistake because of a technical hitch. The suggestion, the possibility, of imperfection seemed to illuminate a more distant horizon, and to add wonder to contentment.

ROYAL SANITARY INSTITUTE CONGRESS

HEALTH SERVICES UNDER THE NEW ACT

The annual Health Congress of the Royal Sanitary Institute, held at Brighton during the week beginning May 23, attracted an attendance of about 2,400, including delegates from foreign, dominion, and colonial governments, home Government departments, nearly 1,000 local authorities, and universities and voluntary organizations. The eight sections were devoted respectively to preventive medicine, engineering and architecture, maternal and child health, veterinary hygiene, food and nutrition, housing and town planning, tropical hygiene, and hygiene in industry. There were special conferences for medical officers of health, engineers and surveyors, sanitary inspectors, and health visitors.

Preventive Services "Played Down"

In the Preventive Medicine Section Professor Andrew Topping, of Manchester University, devoted his presidential address to the National Health Service. He declared himself an ardent protagonist of a State medical service.

"I was, and still am, in favour of a salaried service, and, although the profession as a whole has violently opposed this view, I believe that more and more of the thinking element are beginning to realize that the advantages would far outweigh the disadvantages, and that were it introduced, it would immediately remove many of the difficulties, financial and otherwise, which now beset the Service."

Professor Topping's criticism of the present Service was that its emphasis was entirely wrong. Curative medicine was very generally given pride of place, and prevention was very much the poor hanger-on. "The great majority of doctors would welcome the opportunity of taking an active part in disease prevention, but they are so snowed under with routine treatment of trivialities that the urge quickly dies and consciences become hardened." He found it depressing to read of complaints from a doctor that if he was called to see a child the mother expected him to discuss her own health and that of other members of the family. The complaint was understandable under present conditions of overwork, but it would have shown a better appreciation of realities if the doctor had regretted his inability to meet the mother's wishes and had not dismissed them as intrinsically wrong.

"The Minister of Health has tacitly given his blessing to the present state of affairs by taking unction to his soul for the astronomical increase in the number of bottles issued since the inception of the Service. We all know perfectly well that this feature is very far from being indicative of an improved health service, and it is unfortunate that the great mass of the unthinking public are being confirmed in their erroneous impression that it is so. With very few, if any, exceptions, major improvements in the health of the people have been attributable to betterment of the general standard of living and to the preventive health services rather than to the work of general practitioners or hospital staffs."

The marked fall in the number of students taking the D.P.H., Professor Topping added, was indicative of the difference between the remuneration offered to the newly qualified assistant in general practice, who could get a salary of about £1,000 a year, and to the assistant medical officer, who must have been qualified for at least three years, and preferably should hold a higher qualification, and was offered a salary of £700. It was tragic that one of the immediate, though unforeseen, effects of the new Act had been to "play down" the preventive services and dissuade young medical men and women from making preventive medicine their career.

He attacked with equal vigour the Minister's mistake in not giving priority to health centres with housing, and concluded with the remark that "if we are still demanding more hospital beds ten years from now our health services have been a failure."

Research in Public Health

The opportunities for research in the sphere of public health were discussed by Dr. C. Metcalfe Brown (M.O.H., Manchester). He mentioned the recent investigation in which Manchester had co-operated with a number of other towns in various parts of the country in research, originated and

controlled by the Medical Research Council, into the efficacy of whooping-cough vaccines. This was an admirable example of teamwork, bringing in several universities, public health laboratories, and local authority health departments. In Manchester alone 6,000 children had been included in the trials. Again in Manchester and in other areas trials were being made of a British gamma globulin for the prevention and modification of measles in young children, and in the near future an investigation into the safety and antigenic potency of new diphtheria prophylactics was to be undertaken. Twelve county boroughs had agreed to use in their respective areas one of two new phosphate-adsorbed toxoids and to investigate over one or two years the reaction rates, any untoward sequelae, and the incidence of diphtheria among the inoculated.

Sir W. Allen Daley (Chief Medical Officer, L.C.C.), in an address to a conference of medical officers of health, said that the new Act had come into operation with much less disturbance and friction than many expected. This was due to the abundant good will which had been displayed by all concerned and a single-minded desire to make this great experiment a success. Medical officers of health were anxious to proceed with the provision of health centres, and in this connexion joint consultations between the executive council and the local medical and dental committees were needed. Except on large new housing estates, to which doctors would have to be imported, it was necessary to ensure that the local doctors wanted to work in and from a health centre before steps were taken to acquire and adapt property or erect new buildings. Some health centres must be got into commission quickly so that experience might be gained by experimenting with various types.

One of the most important sections of the Act, Sir Allen Daley continued, was that which dealt with "care and after-care." This had already created many difficulties. First, there was the differentiation between convalescent-home treatment provided free of charge by the hospital authority and admission to holiday homes for which the health authorities were recommended by the Ministry to make a charge. Medical opinion on whether convalescence or a holiday was needed in an individual case might well differ: He looked forward to the day when preventive measures could be applied to many more diseases than was now possible, and when every patient discharged from hospital would pass to the joint care of the general practitioner and the aftercare officers of the health authority.

In a reference to the midwifery service, Sir Allen Daley urged that there should be greater uniformity in the criteria required for admission to the list of general-practitioner obstetricians. Some committees, he understood, had approved all applicants, while others had been quite rigid in requiring that those admitted to the list should have had special postgraduate experience in obstetrics. The extent of the responsibilities to be carried by the midwife and whether or not she was allowed to be the "specialist in normal midwifery" would determine the quality of future entrants to the profession.

Institutional Midwifery

The case for and against institutional midwifery was argued by Dr. J. Stevenson Logan (M.O.H., Southend-on-Sea). A high proportion of institutional deliveries was not necessary for the achievement of low maternal and neonatal death rates or still-birth rates, as was shown by experience in Holland, where 80% of the babies were born at home. The abnormal or complicated pregnancy would always call for treatment in hospital, and, while overcrowding existed, the ordinary decencies demanded maternity beds. But on the other hand the woman confined in hospital or in a maternity home was deprived to a greater or less degree of the close contact with her baby in the early days of its life, and opinion among paediatricians and psychologists alike seemed to be that the importance of this factor had been overlooked by the more enthusiastic advocates of institutional confinements.

"Looking at it from the community point of view, can we afford at this juncture, when hospital provision is so desperately needed for those who cannot in any circumstances be adequately cared for and relieved at home, to contemplate the unregulated increase of maternity beds, which can only be made at the expense of other hospital provision?"

Dr Logan also touched on the question of analgesia and mentioned that one of his midwives told him that since the publication of details about the recent royal confinement the demand for analgesia had been stimulated. If this was at all true of the country as a whole, it showed how perilous it was to be dogmatic about what was really necessary or what women really wanted. It was clear, however, that arrangements for analgesia required strengthening, and it might be that the awareness of the midwifery profession as a whole required quickening. The state of affairs when a woman who genuinely desired analgesia was denied it should be ended as quickly as possible.

Points from Other Contributions

A section under the presidency of Professor Thomas Ferguson, of Glasgow University, discussed hygiene in industry. Professor Ferguson said that the total number of disabled persons in the United Kingdom was about 900,000, of whom 8 to 9% were unemployed. About 40% of the disabled were surgical cases, and 25% medical, with smaller proportions falling into psychiatric and other groups. He described the various residential centres for rehabilitation and the sheltered workshops, such as Hillington, near Glasgow.

Mr William Gissane gave an account of the work of Birmingham Accident Hospital. He urged that the staffs of casualty and fracture departments should be trained at a central accident hospital. Some of these departments, he said, were first-class, others good, and some frankly bad, but they were a vital part of any regional accident service. Dr Maxwell Jones described the work of the industrial neuroses unit which had been established for two years at Belmont Hospital Sutton. The average length of stay was about three months. It was not expected to cure these patients, who were generally chronic neurotics, but to help them to become reasonably independent and self-supporting.

Under the presidency of Professor P. A. Buxton, a Tropical Diseases Section discussed principally the question of malaria control. Dr P. C. C. Garnham said that in Northern Greece the present steep fall in the incidence of malaria was ascribed to natural conditions and only to a very limited extent to the DDT campaign. At the same time the attack on the mosquito by the new insecticides seemed to be fulfilling its early promise.

INDUSTRIAL REHABILITATION UNIT

The Ministry of Labour opened an Industrial Rehabilitation Unit at Leicester in the middle of September, 1948. At first only non-resident cases were accepted, but from Jan. 17 of this year residents have been accommodated also. The non-residents are men and women from the surrounding area within a radius of about 15 miles. At present there are between 50 and 60 of them. The residents come from any part of the country—chiefly the North and Midlands—and only men are taken, there are 43.

The unit is controlled and financed by the Ministry of Labour and National Service. The manager has been chosen for his long experience of industrial conditions and additional experience of training men. He is not medically qualified. A part-time medical officer employed by the Ministry of Labour visits the unit daily. He also has a wide knowledge of industry. There is a rehabilitation officer, whose background again is industrial, not medical, and a Ministry of Labour D.O. is also part of the team. A whole-time State registered nurse looks after the patients and does any first aid that may be necessary, and a trained dietitian is in charge of the kitchen, which can provide special diets—for example, for patients recovered from peptic ulcer. A trained social welfare worker helps the patients over their domestic difficulties, visiting their homes to gain further information if necessary. There are in addition group supervisors who look after the patients in the workshops and garden.

Source of Patients

The patients fall into two main groups though the distinction is perhaps artificial, since there are all grades between the extremes. First, there are men who have passed the convalescent stage of some disorder but are left with a residual

disability, often only psychological. These patients may have suffered from anything—fractured bones, the loss of a limb, tuberculosis—any medical or surgical disorder. Secondly there are the patients who may have some long-standing defect and who have gradually become unable to work satisfactorily in industry. The condition itself may have become no worse, but the man's attitude to it has. More than half of the patients in both categories suffer from some form of neurosis or have psychopathic personalities.

The main channel of entry is through the employment exchanges. These are primarily men who have suffered some illness or accident and find they are unable to obtain a job in industry. Sometimes factories get into touch with the I.R.U. direct. In both circumstances the opinion of the employment exchange or factory must be backed by a medical opinion from the man's own general practitioner or a Ministry of Labour medical officer or a factory medical officer. If the man is referred by a factory or in any other way—for example, by his general practitioner—the unit then refers the matter to the man's local employment exchange and obtains information from them.

In assessing whether a man is suitable for rehabilitation the unit's first consideration is the ultimate chance of the man's employment when he leaves the unit. This is assessed on the information obtained from his local employment exchange and great weight is attached to it. If there is little likelihood of the man's being employed in his trade in his own locality, and if he is unwilling to move elsewhere, he would not be accepted by the I.R.U. The I.R.U. does not train him for a new trade.

Work at the Unit

When a man arrives at the unit the medical officer examines him and tells the manager what the man cannot do—for example, work in a dusty atmosphere, sit in draughts, or stand for long. He also lays down a scheme of remedial exercises and treatment if necessary. The man is given an informal welcome to put him at his ease and put on diversionary work. This consists of some simple task, usually in the garden under the supervision of the gardener. Meanwhile the social welfare worker investigates his domestic difficulties and the group supervisors watch his behaviour. His characteristics are then assessed, and the man is put on to more specialized work such as handicrafts, bench or machine engineering, woodwork, and so on. He may be tested with Raven's matrices, if necessary.

The course lasts up to twelve weeks, though the average is seven to eight. Towards the end of this time the man is put on a job in the unit, but often in contract with a firm outside. He then earns the normal wages and works the normal hours of industry. This stage is introduced to make him feel that he is once again a part of industry, and his future employer may be invited to see him at work and talk to him. So far 90% of the men and women have been returned to their old jobs, placed in other jobs, or sent for vocational training. Only intelligent and young patients pass to the vocational training centre. Of the remaining 10% some are discharged as medically unsuitable before the course ends, and a very few leave of their own accord.

The unit seems to be successful in making the patients fit for industry again, and particularly in overcoming the feelings of inadequacy from which so many of them suffer. It is following up the results at three- and six-monthly intervals. Though it is too early yet to say how significant they are, they seem to be very encouraging.

The scheme under which new entrants to the South Wales coal fields have to undergo clinical and x-ray examinations is to be extended to recruits at all coalfields in Great Britain. This was announced by Mr Alfred Robens, Parliamentary Secretary to the Ministry of Fuel and Power, who stated that the National Coal Board was building up its own medical service, which already consisted of a chief medical officer at headquarters and a medical officer in all the larger coal divisions. He said that fatalities in mines had gone down from the average of 1,200 a year between 1900 and 1920 to 467 in 1948, the lowest figure ever recorded. It should not be overlooked, however, that coal-mining is relatively still the most dangerous occupation and accounts for about one-quarter of the total fatal accidents occurring in industry.

Preparations and Appliances

A BRONCHIAL SUCTION CATHETER

Dr. J. L. GRIFFIN, senior anaesthetist, Taunton Hospital, writes: The instrument here described was designed primarily for routine use by the anaesthetist towards the end of upper abdominal operations and in chest cases, with the aim of preventing atelectasis. The catheter consists of a straight metal tube 27 cm. long, with a bore of 3 mm. The distal end is a rubber-covered flexible cable 7 cm. long, with an inherent curve and an atraumatic sucker end. A pointer at the proximal end

indicates the direction of the curve (see diagram). The instrument is light in weight, so a heavier screw-on handle extension is supplied, which helps

to counterbalance the rather heavy tubing from the sucker machine. Delicate control is thus obtained.

This catheter, tried out on the bronchial tree of the dissected lung, passed with certainty each time into the desired bronchus. X-ray photographs following a partial gastrectomy confirmed this. When air alone flows unobstructed through the catheter the suction apparatus develops a negative pressure of 8 in. Hg. It picks up thick mucus easily, and will pass down a No. 6 Magill tube if required.

Technique of Use.—The instrument should be well lubricated for its whole length by a water-soluble jelly. Extra lubricant is required if it is to pass through a Magill tube. The larynx is exposed by a laryngoscope (Macintosh) and, if necessary, the upper lip is held out of the line of vision by an assistant. Once the tip of the catheter is through the cords the laryngoscope may be withdrawn if desired and the suction switched on. By moving the catheter gently up and down the trachea, and rotating it at the same time, any mucus lying there is removed, since the sucker tip is constantly in contact with the tracheal wall. (For this reason it is more effective than the standard gum-elastic endotracheal catheter for tracheal toilet.) The catheter is next passed down into the right and then the left bronchus by making use of the pointer, and for more efficient suction of the branches may be rotated in this position; it should be kept moving while suction is applied.

The instrument is very useful in cases where, owing to faulty technique or mishap, blood or pus enters the trachea, and when stomach contents are inhaled. Its use in children for the instillation of lipiodol has not been investigated, but it may have possibilities. Probably less lipiodol would be needed, with consequently less interference with respiration. Any excess lipiodol could be immediately aspirated.

Messrs. Charles King have arranged to make this instrument for me.

Reports of Societies

TREATMENT OF CARCINOMA OF VULVA

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on May 20, Professor HILDA LLOYD presiding, a discussion took place on the treatment of carcinoma of the vulva.

Mr STANLEY WAY, of Newcastle-upon-Tyne, said that it was ten years since the subject was discussed in the Society, and in the intervening period there had been considerable changes of opinion. There was an increasing awareness that radium and x rays could do little to effect cure of carcinoma of the vulva. The fearful necrosis which so often followed their application, even in reasonable doses, must be well known. It appeared that surgery was the method of choice. No other site, not even excluding the breast, was more suitable for radical surgical attack. Mr. Way then confined his remarks to the extended radical operation which he had practised for the last

six years. It involved a very wide removal of the vulva and resection of all superficial inguinal and sub-inguinal lymph nodes. He had devised this extended operation as the result of studies which he was able to make in Newcastle. The results of less radical procedures were not encouraging, and the futility of minor surgery he thought was fully demonstrated. The incidence of lymph-node involvement in 88 cases which he took over while working out his technique was found to be 51%.

Cases in which he had carried out his extended operation numbered just over 60. He had rejected or excluded 11 cases, so that his operability rate was 85%. After 64 operations there were 10 deaths before discharge from hospital, including one after uncompleted operation and one death from cerebral haemorrhage three months after operation. The operative mortality might be considered high, but it must be remembered that these patients had very little hope without surgery. The chief cause of death had been wound infection. He hoped that streptomycin would help in this connexion, but it was certainly not a drug to be used indiscriminately as penicillin was used at present. Only 12 of these cases had been operated on five years ago. The five-year survival rate was 83%; the three-year rate 88%.

Most of the extended operations were done in one stage, and he was very much in favour of this if it could be done safely. He had no wish to minimize the difficulties of the operation if it was to be carried out thoroughly in one stage. The longest time he had taken for the one-stage operation was three hours; the shortest, one hour and 10 minutes. But far more complicated and exacting than the operation itself was the aftercare of the patient.

Incidence

The Registrar-General's figures, Mr. Way said, showed that about 400 women in England and Wales died from this form of cancer every year. This was almost certainly an underestimate, for often such deaths were returned as due to cancer of the vagina or uterus. He believed that there might well be 600 cases annually, but even this was not a large figure when distributed over the whole country. At the previous discussion in the Section in 1939 Professor F. J. Browne had suggested that, as the disease was not common, all the cases in an area should be sent to one hospital where special interest was taken in such conditions. The speaker had been able to persuade his colleagues in Newcastle to do this, with the result that he had seen 127 cases of carcinoma of the vulva in the last ten years. He had recently written to a number of centres in Great Britain to find out how often carcinoma of the vulva was seen, and he found that in a number of teaching hospitals in London the gynaecological surgeon saw an average of only about one case a year; in provincial centres the average was slightly larger. Whatever method of treatment was employed, one case a year for each gynaecological surgeon would not offer sufficient experience in either treatment or nursing. He concluded by expressing the view that many more cases could be treated surgically than at present.

On the question of incidence, Mr. A. P. BENTALL said that possibly the incidence varied in different parts of the country, and it might be that in the eastern counties it was higher than elsewhere. In 1945 in the Norfolk and Norwich Hospital there were 10 cases of carcinoma of the vulva, 11 in 1946, 6 in 1947, and 11 in 1948—an average of 9.5 cases a year out of an average of 707 cases of malignant disease.

Mr. J. B. BLAKLEY presented an analysis of cases seen at the Chelsea Hospital for Women and the Royal Cancer Hospital during the period 1933-47. Anything like a complete analysis was impossible owing to deficiencies in the follow-up. At Chelsea out of 29 patients treated during this period the number of five-year survivals was 11 (38%). Early cases with no clinical evidence of involvement of the inguinal glands and treated by simple excision numbered 10; of these, 5 patients had died and 1 was untraced, giving a five-year survival rate of 40%. The results at the Royal Cancer Hospital were similar. Out of 49 patients the five-year survivals were 23 (47%); again a number of cases were untraced. Among 8 early cases treated by simple excision of the vulva or some part of it there were 4 deaths, giving a five-year survival rate of 50%.

The choice in treatment lay between radical surgery and, if the patient was unfit for excision of the vulva, telerradium. In fact, with modern anaesthesia, few elderly women were unfit for surgery. He hesitated to disagree with Mr. Way, but he did not think that in the majority of cases it was necessary to remove the iliac glands, which were involved only very late. He also drew attention to the Stockholm technique, especially a paper by Berven in 1947 on electrocoagulation of the vulva and the application of telerradium to the groin. With electrocoagulation there was surprisingly little shock and pain, and a good deal of sepsis was avoided.

The first general principles for treatment of cancer of the vulva were that the whole vulva must be excised, preferably with the diathermy knife, or else destroyed by electrocoagulation. He preferred the former technique in most cases. The inguinal glands must always be removed. It was possible to start treatment with telerradium one week after excision.

Radical Excision

Mr. ALAN BREWS said that he encountered very few cases of malignant disease of the vulva, but like Mr. Way and many others he was dissatisfied with the poor results of superficial surgical procedures and with radiotherapy. In recent years he had been practising a moderately radical surgical excision of the vulva, with block resection of superficial and deep lymphatic glands from both groins. He had performed this type of operation 12 times—on an average two or three times a year. He had always used combined spinal and light general anaesthesia. He had used diathermy extensively for all skin incisions, and coagulation for all but the largest vessels. He had aimed at the removal of all superficial inguinal and femoral glands; he had not as yet removed the external iliac gland. He had always removed the upper part of the internal saphenous vein. The wound was kept at rest for as long as possible. Only after three weeks, with healthy granulations everywhere, did he allow the patient up, wearing a loose linen garment. She was then sent to a convalescent home for about six weeks, when healing was usually complete.

His cases were too few and recent for useful statistics, but he thought the results encouraging. He had had one primary death, with very extensive local recurrences within a month of the original operation, but he had had no other serious complications as yet. The absence of pyrexia and serious infection and the complete freedom from pain had been notable. His small series included two cases of malignant melanoma; both died within a year of operation, one with a mass of recurrences in the bladder and the other with widespread visceral secondaries in the lungs and liver. He endorsed Mr. Way's plea for concentration of these cases in a few units where an experienced team would give each patient a greater chance of useful survival. It might be that in each region only one such team would be needed.

After some general discussion, Mr. WAY, in reply, said that he could not help feeling that there was still an element of caution abroad. On the subject of palpable nodes, 36% of his cases in which nodes were not felt in the groin were nevertheless found to have cancer. The Berven treatment relied on the palpation of lymph nodes to ascertain whether or not there was involvement. He had never seen lymph-node involvement respond to x-ray or radium therapy. Until the cautious attitude towards the surgery of carcinoma of the vulva was overcome results would not improve. He added that this was a disease which could be practically eliminated by the surgical treatment of leukoplakia beforehand.

The Minister of Health is worried about the amount of time spent by members and officers of local authorities attending conferences. A letter from the Ministry asks local authorities to send representatives only to those conferences at which attendance is desirable in the interests of the council and that the number sent is no more than is sufficient for this purpose. Save in very exceptional circumstances the Minister would not sanction payment for sending representatives to conferences held abroad. The Minister hopes that councils will use their influence where possible to limit the duration of conferences and to see that they are held in reasonably accessible places.

Correspondence

Jenner and Medical Science

SIR.—Sir Edward Mellanby's oratorical contempt (May 28, p. 921) will not suffer him even to name the man whom Bulloch (not Bullock) thought the most learned man he ever knew. Poor Creighton! I must face alone, with such fortitude as I possess, the charges of forming "imbalanced" ("unbalanced"?) and wrong judgments, of having little knowledge of and making little allowance for human nature, and of killing Kruger with my mouth. I do not suppose many people have read my book—it is out of print and likely to remain so. I am not sure Sir Edward has read much of it. I dare say righteous anger led him to cast it aside before he reached my final conclusion that "Jenner was, directly or indirectly, the means of saving many hundreds of thousands of lives"; I added, "That is a less grandiose conclusion than some others have reached, yet, I submit, quite enough to entitle Englishmen to take pride in the recollection that Jenner was their countryman."

However, I still think Jenner was loose-thinking and, ultimately, fact-blind (not fact-blinded, as Sir Edward writes), and to explain how I reached this imbalanced, or unbalanced, judgment will not take much space. In 1798 Jenner wrote to a foreign physician: "At present I have not the most distant doubt that any person who has once felt the influence of perfect cowpox matter will ever be susceptible of that of smallpox."

As Sir Edward so rightly says, we must judge a man by what was known, or probable, when he wrote, not by what later experience proved. When Jenner wrote, it was known that natural smallpox did sometimes attack inoculated persons, and instances of two attacks of natural smallpox in the same person had been recorded. It was, I suggest, loose thinking to infer from his experiments that the new prophylactic was more efficient than the "natural" prophylactic. He might reasonably have hoped that it was equally efficient and less dangerous.

It was, I suggest, to be fact-blind to have written a quarter of a century later, after all that had happened:

"My opinion of vaccination is precisely as it was when I first promulgated the discovery. It is not in the least strengthened by any event that has happened, for it could gain no strength; it is not in the least weakened, for if the failures you speak of had not happened, the truth of my assertions respecting those coincidences which occasioned them would not have been made out."

Sir Edward tells us that "the test of the acceptability of a discovery depends upon whether it is true and not whether it seems sensible or even whether it can be verified by the statistician." Or, in other words, a discovery is acceptable if it is a discovery. Certainly many discoveries—e.g., in the field of ethics—cannot be verified by statisticians, or even by biochemists, but is the discovery of a prophylaxis one of them? Pearson and Woodville in Jenner's time did not think so; the Medical Research Council in our time does not seem to think so.—I am, etc.,

Loughton, Essex.

MAJOR GREENWOOD.

Treatment of Basal-cell Carcinoma

SIR.—In our article in the *Journal* of April 30 (p. 737) we stressed in the title the "especial reference to lesions on the neck, trunk, and limbs." For this reason we made no further reference to the 210 cases in which the tumour was situated on the face or scalp.

It is as a primary treatment of rodent ulcer that we especially recommend surgical excision. The following two tables are compiled from the personal case records of one of us (C. W.). They refer to basal-cell carcinomata on the face and scalp treated between 1915 and 1935: a complete "follow up" was conducted in 1938.

The first table shows the results of surgical excision as primary treatment of rodent ulcer; they are surely better than those shown by radiotherapy. The statement that "there should be no recurrence with adequate surgical excision" is

TABLE I.—Results of Treatment by Primary Excision

	No. of Cases Treated	Not Traced	Died of Inter-current Disease	Recurred	Recurrence Free	Percentage Free from Recurrence
Patients treated between 1915-1925	51	18	10	1	22	96%
Patients treated between 1925-1935	62	20	16	0	26	100%

TABLE II.—Results of Treatment by Excision Following Failure of X-ray Treatment

	No. of Cases Treated	Not Traced	Died of Inter-current Disease	Recurred	Recurrence Free	Percentage Free from Recurrence
Patients treated between 1915-1925	25	10	4	5	6	54%
Patients treated between 1925-1935	35	14	7	8	6	43%

more than an "expression of hope." If the excision is adequate there is no pathological basis for recurrence—all the tumour cells have been removed. Professor D. W. Smithers's figures (May 14, p. 865) show how difficult it is to eradicate all the tumour cells by radiotherapy.

The second table illustrates one of the special hazards of radiotherapy. Recurrences following x-ray therapy as the primary treatment are much more difficult to eradicate. Further recurrences are only too liable to occur. This is the sort of case that Professor Smithers will pass over to the surgeons. Perhaps this is what Professor Smithers means when he says, "Surgeons and radiotherapists do better by working together." In many fields we are only too ready to agree with him, but not in the treatment of basal-cell carcinoma.

We do not agree that irradiation gives a better chance of cure in lesions on the eyelids. Surgical excision will cure the patient, with far less chance of recurrence than irradiation. In the past irradiation produced a good cosmetic result more often than surgery; but with the development of plastic surgery the cosmetic results of surgery can now compete with those of irradiation.

So often, and Professor Smithers's figures show how often, irradiation results in delay in cure and makes further treatment more difficult. Therefore we recommend that all rodent ulcers should be excised when first seen. And if the patients are "worried" they may be "premedicated," for it is worth curing them at their first treatment.—We are, etc.,

CECIL WAKELEY.
PETER CHILDS.

London, W.1.

SIR,—On reading the recent correspondence concerning the treatment of rodent ulcer I was reminded of an interesting case, a female mental patient, who was admitted to hospital at the age of 51 in 1938.

At this time she showed a pale scar in the left infra-orbital area of the face about which she was unable to give any information, and as there were no signs of any pathological activity it was ignored. Towards the end of the year 1944 a new lesion was observed, this time on the forehead over the left eyebrow, but it showed little reaction and did not appear to warrant much closer investigation. However, its chronicity led to the calling of a consultant, who diagnosed rodent ulcer in 1947, and radium therapy was prescribed. This was carried out in the Christie Hospital, Manchester, the patient visiting for sessions of treatment once a month, commencing in September, 1947.

In December of that year a third ulcer appeared in the right infra-orbital region, and therapy was applied to this also. In January, 1948, the irradiation produced a conjunctivitis and blepharitis on the right side necessitating local palliative treatment, and the sessions were discontinued temporarily. In March, 1948, a further lesion appeared on the left side of the nose, which was watched carefully; surprisingly it regressed, and healed of its own accord. In June, 1948, the lesion over the left eyebrow succumbed to a simple pyogenic infection, which was treated locally with gentian violet with success, and in September the irradiation therapy was discontinued, as the ulcers had healed.

The patient has been examined by the consultant at three-monthly intervals since, and no further activity has been observed, nor has there been any glandular involvement up to March, 1949. She will be seen again in June, but the prognosis is considered very good.

The interesting point about this case seems to be the recurrence of the same disease in different but close areas, and the possibility of minute traces of active pathological tissue being still *in situ* after apparent healing gives rise to the suspicion that direct spread has insidiously taken place. The directions of spread are such as to make this supposition improbable, so that one is forced to assume each lesion was a neo-neoplasm *per se*. Perhaps some reader might clarify this point.—I am, etc.,

Winwick, Lincs.

P. A. M. ROBERTSON.

Penicillin-resistant Staphylococci

SIR,—Dr. N. G. B. McLetchie (April 23, p. 725), in criticizing our use of the word "strain," has raised a matter of general interest. He appears to wish to limit its use to that usually given to "type."

The word appears to have two slightly different meanings, both of which may be used without ambiguity. This was done by Dr. G. Martyn (April 23, p. 710), who writes, "The high incidence of penicillin-resistant strains probably reflects the strain circulating in the hospital." Here strain in the second place bears the meaning "kind" or "sort" and suggests that had typing methods been available the circulating strains might have belonged mainly to one particular type.

Allison and his colleagues use "strain" in a quite different sense from "type"—a type including many strains from different patients. In summarizing an outbreak of staphylococcal food-poisoning these authors state that "the 125 strains submitted or isolated were typed by serological and bacteriophage methods. . . . 113 belonged to the serological type III, phage type 6/47" (*Mon. Bull. Min. Hlth*, 1949, 8, 38).

It is legitimate to regard any single organism on a swab as potentially a strain, just as in horticulture each individual seedling in a stand may give rise by vegetative propagation to a clone. It is here that difficulty arises in comparing the figures given by different authors. While one worker may accept into a series several strains from swabs and cultures from different parts of the body of a single patient, another will add only one to his collection. The figures will then require very careful analysis if a comparison is to be made.

We have taken a total of 315 strains from 241 persons. This in practice means that each patient gave at least one strain and sometimes two. The second was added if some definite difference in colonial appearance could be observed and reproduced in subculture, or if some definite difference in penicillin sensitivity or in coagulase production were present.—We are, etc.,

Transfusion Compatibility Tests

SIR,—A recent case observed at hospital illustrates how an error in rhesus grouping, together with reliance on the saline compatibility test, led to the administration of rhesus-positive blood to a rhesus-negative individual previously immunized by repeated blood transfusions.

A man aged 34 had suffered from ulcerative colitis since 1944. On four previous occasions 19 pints (10.8 litres) of group A blood had been transfused without any reaction other than mild pyrexia without rigor; on the last occasion the temperature after transfusion had reached 102° F. (38.9° C.), and a mild asthmatic attack had occurred. On April 6, 1949, the patient was again admitted for transfusion. An experienced laboratory technician recorded his blood group as A rhesus-positive, and accordingly a compatibility test using patient's serum and donor cells suspended in saline only was employed. This showed no incompatibility after one hour at 37° C. The blood was accordingly issued as compatible. After about 50 ml had been transfused the patient experienced a rigor and complained of severe throbbing headache with pains all over his body. The temperature rose to 102° F. (38.9° C.). In view of this reaction the ward sister stopped the transfusion after 150 ml. of blood had been given. Recovery was uneventful. The following day a sample of patient's serum was again incubated with the donor cells, after which an indirect Coombs test was done. This showed very strong agglutination of the donor erythrocytes. Subsequent investigation showed the patient to be in reality rhesus-negative, and his serum to contain anti-Rh (anti-D) blocking antibody active against the cell transfused in a dilution of 1/80. The donor cells suspended in 25% bovine albumin were strongly agglutinated at 37° C. by his serum.

within five minutes. On April 11 the titre of the antibody had risen to 1/5120.

This case strongly endorses the plea made by Drs. B. Godwin and A. J. McCall (May 14, p. 870) that all compatibility tests should be made as a routine with the donor cells suspended in bovine albumin. Had this been done in the above case the error in rhesus grouping would have been easily detected and the false sense of security engendered by the erroneous rhesus test on the patient would have been rapidly dispelled. Now that 30% bovine albumin is available commercially in this country it would seem to be the duty of all pathologists and transfusion officers to abandon the time-honoured but fallacious saline compatibility test—I am, etc.,

Worcester

P. KIDD

SIR,—Many will disagree with the statements made by Drs. B. Godwin and A. J. McCall (May 14, p. 870). The case reported by Drs. A. C. Buchan and John Wallace (April 16, p. 660) can hardly be said to illustrate the danger attending the use of saline cell suspensions in a direct compatibility test. There is no evidence that albumin-agglutinating antibodies were present in the circulation before the transfusion, and even if they were it is by no means certain that they would have been detected by a rapid compatibility test using an albumin cell suspension.

What it does illustrate is the danger in omitting to test the patient's Rh type. Had this test been done there should have been no transfusion reaction, since Rh-negative blood would presumably have been administered.

Any rapid direct compatibility test is likely to prove "unsatisfactory and dangerous" if too much is expected of it. Such a test should provide a safeguard against gross technical or clerical errors—e.g., a mistake in ABO grouping or the wrong label on a bottle of blood—errors happily rare and, indeed, rarer than those inherent in the compatibility test itself. It is not, however, an adequate test for detecting Rh antibodies and will often fail to do so.

Thousands of tests on pregnant women carried out in this laboratory, using Diamond and Abelson's technique in parallel with the standard tube and Coombs techniques, have shown that while the first is an excellent rapid method of ABO grouping and Rh typing when potent antisera selected for the purpose are employed it not infrequently fails to reveal the presence of Rh antibodies even when sensitive cell suspensions are used. It will fail more often in direct compatibility tests, where one is dealing not only with antibodies of unknown potency and speed of reaction but with stored cells of unknown sensitivity.

Nearly all dangerous transfusion reactions, not due to ABO incompatibility, occur in Rh-negative (D-negative) persons, and these can be avoided by D-typing and transfusing Rh-negative blood. In urgent cases the method of Diamond and Abelson is satisfactory for this purpose; and since supplies of suitable anti-D sera are available there is little excuse for failing to carry out a test of this kind before blood transfusion is undertaken.

The problem of the rare Rh antibodies occurring in D-positive persons, and the still rarer anti-Kell and anti-Lutheran, is not solved by the albumin compatibility test. Such a test, if carried out in the hope of detecting rare antibodies in cases requiring urgent transfusion, might well be confined to those with a history suggestive of immunization (transfusion or pregnancy) or where no history can be elicited. And its limitations must be appreciated. In the case of planned transfusions more accurate and sensitive techniques would naturally be employed.

It cannot be emphasized too strongly that D typing is of prime importance and should never be omitted. By the use of this test Rh-negative blood will be conserved, dangerous immediate reactions due to the presence of anti-D eliminated, and the more remote but equally real danger, so often ignored, of immunizing patients against the D factor will be avoided.

Drs. Godwin and McCall state: "The use of a satisfactory compatibility test is therefore a more important safeguard against dangerous reactions than is routine Rh testing with a limited range of sera, for only in this way can the reactions due to the rarer Rh antibodies and other irregular agglutinins

be avoided." If this is taken to mean that D typing can be omitted provided the direct compatibility test recommended by them is carried out, those who follow this advice will be casting away the substance for the shadow, and the artificial immunization of Rh-negative persons will still continue.—I am, etc.,

Blood Transfusion Centre, Sheffield

R. H. MALONE.

An Unfortunate Precedent

SIR,—Dr. A. P. Cawadias (May 21, p. 910) refers to the appointment of the President of the Royal College of Physicians to the Awards Committee as not an "unfortunate precedent." Later on in his letter he states, "As in the course of centuries the College changes its mode of action, abandoning its academic ivory tower, it has to come more into the open struggle." Surely the "unfortunate precedent" is in reality this fact, and that the College has seen fit in doing so to act in a manner in direct opposition to the expressed desires of the whole medical profession, in consequence it has lost in some degree the respect and confidence of the profession.

The College of Physicians is a very specialistic body, and as such should not presume to meddle with professional administration, which requires wide knowledge and practical experience of affairs not to be gained by the examination and training necessary for acquiring a specialistic diploma.—I am, etc.,

St Mawes Cornwall

B. H. SHAW.

Curare-modified E.C.T.

SIR,—Dr. S. J. G. Spencer says (May 14, p. 869) that the dosage of *d*-tubocurarine chloride used by us is "dangerously high," but mentions no danger other than respiratory arrest. Our purpose in mentioning the prolonged periods of apnoea which we have occasionally encountered was to show that we do not consider this to be a serious danger if an adequate method of artificial respiration with oxygen, such as we describe, is at hand.

The disadvantages of giving 5 mg of tubocurarine at two-minute intervals seem to us to outweigh any possible benefit. He states that his method produces "adequate muscular relaxation without severe respiratory depression." Adequate for what purpose? The patients whom we treated had physical illnesses which make an insufficiently modified convulsion a much greater potential danger than hypersensitivity. It takes eight minutes to inject 20 mg *d*-tubocurarine chloride by his method. Slow injection of this drug is stated to increase the danger of bronchospasm, its effect on an agitated, uncooperative, depressed patient seems to us to make the treatment unnecessarily unpleasant. The same quantity of the drug injected quickly will not have the same effect as when injected slowly. We agree that the correlation between weight and effective dosage is low, and we now use a standard initial dose of 18–20 mg. for females and 25 mg for males. This is varied occasionally when the physical condition would make greater modification desirable.

Dr. Spencer does not say why he considers "it is important to reach by calculation the correct end-point with thiopentone." Rapid administration of 0.25 g of thiopentone ensures unconsciousness in every patient, while the (remote) danger of prolonged respiratory arrest is adequately guarded against by the Lucas respirator. The method he describes is more time-consuming. We do not use neostigmine as a routine, because of its unpleasant side-effects. Artificial respiration is always carried out by a doctor and with a Lucas respirator is an easy procedure.

We should like to add that since our report we have treated another fifty cases of a similar character with no casualties, and also to refer Dr. Spencer to the large number of cases treated by Drs. Hobson and Prescott,^{1,2} to whom we are grateful for our knowledge of the technique we have described.—We are, etc.,

P. D. W. SHEPHERD

"Death Following Abortion"

SIR,—Will you grant me space to comment on a report (May 7, p. 825) and to correct any misapprehensions which may arise from it? Is it correct to head the report "Death Following Abortion"? The certificate from the general practitioner stated that the patient was pregnant about five months. On examination I formed the opinion that the pregnancy was approaching the twenty-eighth week, and sent her into the nursing-home for induction of premature labour.

The patient was referred by the G.P. to the psychiatrist, with a letter stating that she was mentally disturbed and suicidal. She was referred to me by the psychiatrist, who sent me the G.P.'s original letter, together with a letter from himself saying: "I am perfectly satisfied that her pregnancy should be immediately terminated." Some hours later he sent a detailed report stating: "I consider that it is absolutely essential to terminate this pregnancy, even although it is advanced, to safeguard this young woman's mental stability." I was informed that she had already attempted suicide, but that her mother had unexpectedly arrived in time to rescue her. On the basis of the two medical reports, and the impressions I formed when I saw the mother and the girl, and examined the latter, I decided that immediate termination of the pregnancy was indicated, whether or not the child was viable.

It was not until the inquest, eleven days after the patient's death, that I learned that the matron was not a registered nurse. The certificate of registration of the nursing-home hangs in the entrance hall, and I presumed that the matron herself was registered.

The fact that death did not take place till ten or fifteen minutes after the operation was not only "suggested by the matron," as stated in your report. This was stated on oath by both the anaesthetist and myself.

The Home Office pathologist stated in evidence that an operation of this kind could be carried out at a public hospital, under the National Health Service, without any cost to the family of the patient. That is true. So could any other surgical operation. So could all the operations, of any kind, that are carried out in all the private nursing-homes in the country. But many patients who can afford to pay private fees prefer to have a doctor of their own choice and the amenities of a private nursing-home.—I am, etc.,

London, W 1.

NORMAN HAIRE.

The Lock Hospital

SIR,—It is difficult to entertain with even a modicum of seriousness the idea of closing the National Gallery and transferring the pictures that hang therein to the foyer of the Odeon Cinema. I feel that I am one of the very few who can speak upon the subject of the London Lock Hospital with both a knowledge of, and a disinterest in, the subject. I have been a medical officer in the Lock, but my material association with it terminates within a matter of days.

The Lock is not without a few of the many faults possessed by every hospital. It is served by some doctors who have a wealth of experience not known elsewhere, and by some venereologists whose ability is indisputable; it is also served, and this may be looked upon as one of the hospital's few faults, by some general surgeons whose interest in venereal diseases is secondary. But why pull down a house when the installing of electricity would perfect its structure?

As a teaching centre the Lock has facilities and clinical material which makes it unsurpassed and unsurpassable. And the patients—a minor detail—what of them? They range socially from the highest to the lowest, from the stage to the street, from the sublime to the pediculous. Are they to be consulted? It is a simple matter to take one's spirochaetes around the corner to another clinic—but confidence lacks the motility of the spirochaete, and the confidence of the patients in the Lock is one of the most striking aspects of the hospital. Many patients have been attending for sixty years; the fact that they still attend, indeed the fact that they still live, is testimony of the highest worth. The Lock was not built in a day: to it all roads lead. Let wisdom prevail!—I am, etc.,

RAYMOND OLIVER.

Treatment of Rheumatoid Arthritis

SIR,—I was interested in the leading article (May 7, p. 812) on a new treatment for rheumatoid arthritis. In 1927 the hospital to which I was attached was seeking information regarding the value, if any, of ultra-violet light in the treatment of tuberculous arthritis in children. Attention was drawn to some similarity between certain of the cases and Addison's disease, and it was decided to give whole suprarenal gland to certain cases. The clinical improvement in the first case so tried was so startling that I have always been convinced that there was here a line for further research.

Schafer¹ suggests that the suprarenal capsules have what he calls an "antitoxic" property. The improvement in a series of eleven cases was not so convincing, but was not exactly negative. The work was controlled by blood sedimentation rates, etc.; it was published in the *Archives of Disease in Childhood* (1929, 4, 47).—I am, etc.,

Ormskirk, Lancashire.

JOHN D. CRAIG.

REFERENCE

¹ *Endocrine Organs*, 1924, London, p. 93.

SIR,—Your timely leading article (May 7, p. 812) speaks of a "waning of belief in an all-important infective factor" in the aetiology of rheumatoid arthritis. With all due respect to the belief of others, may I as one who for nearly thirty years has devoted himself to the intimate study of rheumatism reiterate my often expressed view that the role of infection in the causation of rheumatoid arthritis is a very important one?—

Years ago I drew attention² to certain clinical aspects of rheumatoid arthritis which in my opinion point quite clearly to an infective origin. Consequently I laid down certain therapeutic principles (systematically carried out and strictly observed rest, nutritional treatment, etc.) which soon found general acceptance and stood remarkably well the test of time ever since. In the course of years I saw many thousand patients who had been either completely cured or at least saved from permanent crippledom with the help of treatment on these lines. It was thus possible to demonstrate the "reversibility" of rheumatoid arthritis more than twenty years ago.

It is therefore quite impossible for me to understand why it should be "difficult to harmonize the microbic theory of rheumatoid arthritis with modern knowledge." One has, of course, to bear in mind that rheumatoid arthritis is a disease of complex character and of multiple origin. In a small monograph³ I stressed the point that in addition to infection other aetiological factors have to be considered. In this connexion I was much impressed by the fact that certain types of rheumatoid arthritis could be found almost exclusively in young females and others in women in or near the menopause. Nor did I fail to notice the striking differences in the clinical picture of rheumatoid arthritis according to the age of the patient ("growing pains" of early childhood with little or no changes in the joints and practically never a raised temperature; very marked swellings of the joints and tendency to higher temperature in adults; slight clinical changes without high temperature but coupled with extreme painfulness of the joints in old patients). All these facts have clearly pointed to a certain correlation with, and an involvement of, the endocrine glands. It was logical to assume that the disturbed correlation of these glands and the resulting biochemical changes must play a very important part in the pathogenesis of the disease.

It is therefore erroneous to say that "the disease is part of a basal biochemical disturbance of unknown type." In reality "the basal biochemical disturbance" forms part, but one part only, of this complex disease. The fact of the matter is that the two main causative factors, infection and endocrine disturbance, under the additional influence of climate, environment, occupation, etc., bring about an almost capricious variety of clinical picture in rheumatoid arthritis; but in every case it is the impact of the infection which "starts the ball rolling."

In the interplay of the two main aetiological factors the bacterial toxins are playing the role of the "noxious agents" which Selye and others found lately to be able to produce a "general adaptation syndrome." These experiments are really just another proof of the correctness of the "microbic" theory.

The complex aetiological origin of rheumatoid arthritis makes it obvious that no unilateral therapeutic approach can ever yield satisfactory results, and I never missed an opportunity of pleading for a multilateral one. Impressed by the fact that patients suffering from rheumatoid arthritis—if there is no complication by other disease—have almost invariably low blood pressure (in contrast to cases of gouty arthritis, who almost invariably display high blood pressure), also bearing in mind the always present derangement of the internal secretory balance of these patients, for more than fifteen years I used to administer systematically natural anterior pituitary and adrenocortical extracts and have found these hormones to be very effective in the advocated multilateral therapeutic approach.

On the other hand, having seen during thirty years many "new treatments" emerge triumphantly and also disappear "unwanted and unwept," I hope to be forgiven if I utter a word of caution. One must realize that every therapeutic principle—powerful as the action may be within its own sphere—can be effective in one definite direction only, and must of necessity be inadequate to deal with a complexity of pathological factors, as represented in the aetiology of rheumatoid arthritis. When planning treatment for a case of rheumatoid arthritis it will be always necessary to assess and evaluate the *ad hoc* composition of the aetiological mosaic and to arrange the therapeutic arsenal accordingly. As far as I can see—*ut falsa vates sim*—there will never be a "blue print" for the treatment of rheumatoid arthritis, the successful treatment of which for a long time to come will require much special knowledge and circumspection from the physician.—I am, etc.,

Morton's Metatarsalgia

SIR,—In the introductory sentence of the annotation on Morton's metatarsalgia (May 14, p. 858), there is an implication that T. G. Morton was the first to describe this syndrome in 1876. Possibly some of your readers may be interested in the following :

"Another form of neuralgic affection occasionally attacks the plantar nerve on the sole of the foot, between the third and fourth metatarsal bones, but nearest to the third, and close to the articulation with the phalanx. The spot where the pain is experienced can at all times be exactly covered by the finger. The pain, which cannot be produced by the mere pressure of the finger, becomes very severe whilst walking, or whenever the foot is put to the ground.

"Relief can only be afforded by the application of lateral compression, a strip of plaster about an inch wide being drawn tightly over the foot and round the sole. I believe this application acts by drawing the metatarsal bones closer, and thus affording protection to the affected nerve, which, when the parts are capable of expansion, is more exposed to pressure."

This occurs on page 52 of *A Treatise on Corns, Bunions, the Diseases of Nails, and the General Management of the Feet*, by Lewis Durlacher, Chiroprapist to the Queen, and published by Simpkin, Marshall and Co. in 1845, thirty-one years before Morton published his description.—I am, etc.,

London, S.W.3

C. E. KEMP.

Thiosemicarbazone

SIR,—In the many various publications about tuberculosis there is no mention of the drug thiosemicarbazone. This is a new compound suggested by Professor Domagk, of Wuppertal, Germany, for the chemotherapy of tuberculosis. While serving with the R.A.M.C. in Germany I attended the congress of the West German E.N.T. specialists at the University of Bonn. Professor Domagk (inventor of "prontosil") was the main lecturer. He gave a detailed account of his experiments in the treatment of tuberculosis with thiosemicarbazones. He did not disclose the formula of the compound.

Following his lecture, papers were read by clinicians from various medical centres where this drug is used experimentally for treatment. A report from the clinic for the treatment of lupus in Münster stated that the new drug cured lupus in a short time. A professor of otolaryngology reported his ex-

perience in treating laryngeal tuberculosis with thiosemicarbazone. Dysphagia disappeared in 3-4 days after the commencement of treatment, even in the very severe cases. Treatment of pulmonary tuberculosis was disappointing so far.

There is little we can learn nowadays from German medicine, which is unbelievably backward. But there are a few things of importance, and it may be useful to know more about them. It is a great pity that so many British doctors now in Germany with the R.A.M.C. make such little use of their stay there from this point of view.—I am, etc.,

Norwich.

L. FISH.

*An abstract of a paper on thiosemicarbazone by Professor Domagk (*Nord. Med.*, 1948, 39, 1322) appeared in *Abstracts of World Medicine* (Feb., 1949, p. 246).—Ed., *B.M.J.*

Treatment of Varicose Veins

SIR,—I cannot let this correspondence pass without putting in a good word for injection therapy. I feel that letters on any subject in your columns should be helpful rather than condemnatory, and that it would be a pity if such an excellent method of dealing with varicose veins should be damned either by a theoretical boggy of deep thrombosis—which I have never seen—or by the charge of almost certain recurrence.

I have been injecting varicose veins for over nineteen years, and have done well over 20,000 injections, of which I have regretted only a few. Five out of six of my patients come to me or to my clinic at Battersea Central Mission on the recommendation of former patients whose varicoses I have completely cured to their own satisfaction. I even injected my own varicose vein three years ago, and to-day there is not a sign of what was a very large and twisted varix.

I think that the secrets of success are : (a) inject as high as possible; (b) inject very rapidly with the leg in a horizontal position and sweep the wave of sclerosing fluid down the vein and into its tributaries with the hand (this needs considerable practice and confidence); and (c) always apply a compression bandage, usually of the adhesive type, and keep this on for a fortnight. In certain cases this means strapping the limb from the foot to the thigh, or at least as high as the upper limit of the varicosity.

It would be useless to deny that in a small proportion of cases there is a recurrence due to recanalization. But this occurs quite early—usually within six months—and it will be found that the vein wall is thickened and that a second injection, made with the same precautions, will produce a lasting hard sclerosis, and that the offending vein will disappear completely in a few months.

Recurrences also occur after ligation, and quite a number of my patients have had the Trendelenburg operation done previously. But I do not on that account condemn the operation, and it may be that a combination of both methods would result in fewer recurrences than either alone. Finally, let each continue to practise and try to perfect his own technique, and if his results are good he will have no lack of a steady flow of well-satisfied patients.—I am, etc.,

London, S.W.7.

R. SIMPSON HARVEY.

Dried Plasma for Domiciliary Midwifery

SIR,—Even in these days of antenatal clinics and x rays cases of unexpected twins continue to occur in general practice. I recently saw such a case, and found myself delivering uniovular twins in a bedroom at night.

Both arrived without difficulty, but in the third stage there was considerable post-partum haemorrhage due to atonic non-detachment of the placenta. Manual removal was not feasible, and it was then that I was truly thankful that I had with me a supply of plasma to give without delay. Resuscitation, combined with ergometrine, was successful, and the placenta was eventually removed in hospital the next morning. All three are doing well.

May I suggest that all who practise domiciliary midwifery should carry with them a special bag containing at least two pints (1.1 litres) of dried plasma, the necessary sterile water, and a giving set? May I also suggest that midwives should carry plasma and be trained to give it? And it should, of course, be a stock possession of every maternity home.

I am a firm believer in analgesia, but if I had to choose between having a gas or trilene apparatus for the comfort of my patient or a supply of plasma for the safety of her life I should undoubtedly select the plasma. Furthermore, I believe many more women would volunteer to give their blood to the banks if they knew it would be devoted to making plasma for obstetric emergencies in the home. Because of recent political arguments, the general public knows how important analgesia in childbirth is considered. The provision of dried plasma for domiciliary midwifery is, in my opinion, of even greater urgency.—I am, etc.,

Herne Bay, Kent.

C. T. H. WHITESIDE.

Reform of Mental Hospitals

SIR,—I have read the review (April 30, p. 761) by Dr. Edward Glover of Mr. H. G. Woodley's book on the above subject with considerable interest. The review starts off with the phrase, "No doubt there is a good case for the reform of institutional psychiatry," and concludes, "In fact the main virtue of the book is that the author attempts, however unsuccessfully, to do what would be much better done by psychiatrists themselves, if only they were so disposed."

This is the root of the problem. Mental patients are inarticulate, and even when they recover and become articulate their appeal is discounted as being that of persons lacking in judgment; while unfortunately those who are in charge of large mental institutions naturally tend to accept things as they are, and the spirit of radical reform is conspicuous by its absence from the recommendations of the great majority of those who have the care of our unfortunate mentally sick brothers and sisters.

It would be of considerable interest to know how much the National Health Service expends per head on those who are physically ill and how much we spend per head on those who are mentally ill. I feel sure that if the figure were known the public conscience would be startled by the abyss between our concern for the ailing in body and those who are ailing in mind.

The root-and-branch reform of our mental institutions is long overdue, but it will not come until the public conscience is aroused to the urgent need for classification and individual treatment of mental patients in a much greater number of units far smaller in size than the great barracks where to-day all types and degrees of mentally sick persons are herded together for mass control.—I am, etc.,

Wrexham, Denbighshire.

CYRIL O. JONES.

Paediatrics and Family Practice

SIR,—We are very glad that Professor W. S. Craig, Dr. F. Charlotte Naish, and Dr. M. F. G. Buchanan (May 7, p. 801) are attempting to bring the medical student into touch with the problems of family practice. At the same time we fear their initial premise "that the instruction of the medical student is concerned primarily with the training of the family doctor" will not go uncontested. The Medical Curriculum Committee of the B.M.A. states bluntly, "The object of undergraduate teaching is not to train general practitioners, but to provide the student with a foundation for his later career in any branch of medical practice," and it can count on weighty support within the profession.

Yet, lacking a clear directive principle, the insatiable curriculum daily devours apace, threatening the efficiency and zest of teacher and student alike. The nature of this principle is perhaps the most important issue in medical education to-day. As teachers, we frequently ask ourselves the question, "What exactly are you trying to do?" and more and more we are inclined to answer with Professor Craig and Drs. Naish and Buchanan, "To train a family doctor." Once this view is accepted an effective principle of integration is introduced in the curriculum.

We are now trying to discover the amount and kind of disease in children encountered by practitioners in different kinds of practice, and Dr. Naish could probably help us on this point straight away. With this information added to out-patient and ward experience we shall be able to see the paediatric needs of the family doctor in better perspective and arrange our teaching accordingly. Further, deliberate practitioner

training would also permit a more precise answer to the fundamental question which any reform of the curriculum must raise—namely, What should be considered undergraduate and what postgraduate subjects? Nor does this apparently utilitarian approach deprive the student of that basic foundation which the B.M.A. Committee rightly desires. "Medical education, like all education, is primarily an appreciation of method, and secondly a knowledge of fact," and a variety of subjects can provide material equally suitable for the development of that appreciation.

In this department we are engaged also in studying a number of common disorders in childhood as they present to the family doctor, and we are increasingly impressed by the refreshing effect that this has on our work and teaching. What is more, the consistent appreciation of the students during the past two years has convinced us that their essential curiosity and zest for learning have not been weakened by our preoccupation with those common disorders which will be the concern of the majority for the rest of their lives.

The need is not to give the student just a glimpse of yet another clinic, but rather to give him substantial contact with the day-to-day work of family practitioners. We understand that for some time the Edinburgh Medical School has used the domiciliary practice in this way, and their observations would be very welcome. Valid assessment of the success or failure of this method cannot be made quickly; it will be shown in the rising or falling standard of family practice in the years ahead. For this reason we should set little store on the immediate comments of the students or the apparent toleration of their presence by the patients. There is need for careful preparation, experiment, and prolonged observation in this matter. With these reservations, we would like to join with Professor Craig and Drs. Naish and Buchanan in their plea for the fuller use of family practice in undergraduate teaching, and we hope their paper will promote fresh consideration of this important question.—We are, etc.,

S. D. M. COURT.

F. J. W. MILLER.

Newcastle-upon-Tyne.

SIR,—I read with great interest the article by Professor W. S. Craig and Drs. F. Charlotte Naish and M. F. G. Buchanan entitled "Instruction of the Medical Student in Paediatrics" (May 7, p. 801). When I entered my present practice in a working-class district of London in 1937 I found that I seldom saw an infant or young child unless he was acutely ill. Many of my patients were so poor that they waited until their children were very ill indeed before consulting me. I therefore encouraged them to join the London Public Medical Service, in order that, by paying a few pence a week, they would be entitled to medical attention whenever necessary.

Early in 1938 I started to hold my own children's clinic 'one afternoon a week, which my P.M.S. patients were urged to attend as part of the service. Except for my four years' absence in the Forces, the Clinic has been held regularly ever since. The work done is practically identical with that described by Dr. Charlotte Naish in her own clinic—examination and weighing of infants, advice on infant feeding, vaccination, and immunization, and discussion of general health and behaviour problems. Careful records are kept of each case.

I find the mothers most appreciative. They prefer the intimate atmosphere of their own doctor's consulting-room to the rather impersonal one of the infant-welfare centre. Moreover, if am called in to a sick child my work is made the easier by the fact that I know the family, and mine is a familiar face to the child.

Nevertheless, there is one problem which I should be interested to know if Dr. Naish shares. Despite the fact that I stress the importance of regular routine examination I find that when the infants reach the age of one year it is almost impossible to persuade the mothers to bring them to the clinic regularly. Whether because of lack of time or because of diffidence in troubling the doctor, older infants and children are rarely brought to see me unless they appear unwell.

I was, however, most gratified to read of the work being done by Dr. Naish and her partners. My colleagues have often made me feel that my interest in positive health in paediatrics was an amiable eccentricity and that such work belonged rather to

Varicose veins

the most **efficient** injection treatment

Ethamolin offers specific advantages over any other sclerosing agent for varicose veins. Given sufficiently early, Ethamolin frequently brings *lasting* benefit, marked relief can be obtained even in cases of prolonged untreated varicosity. Ethamolin forms a firm, adherent thrombus. Sloughing is not caused if the solution escapes around the vein and there are no general reactions except in the very rare case of hypersensitivity. The total dosage required is normally less than 6 cc. being powerfully bactericidal. Ethamolin reduces the risk of infection to a minimum. With Ethamolin the practitioner is thus equipped to deal with the majority of his varicose patients without need to resort to operative measures.

MONOETHANOLAMINE OLEATE

Progress in Therapy

A CONSTANT AIM of Boots' research department is to explore every possibility in drug production and place the results at the disposal of the medical profession. The following are three recent additions to the comprehensive range of Boots' Medical Products.

1

D.F.P.

Di-Isopropyl Fluorophosphonate

A potent miotic and inhibitor of cholinesterase for the treatment of glaucoma, paralytic ileus and myasthenia gravis.

2

Histostab

A satisfactory antihistamine with few undesirable side-effects, for the treatment of a wide range of allergic conditions.

3

Suspension of Sulphathiazole-Boots

A palatable, finely divided suspension of Sulphathiazole for the treatment of infections in children. Specially prepared to overcome the difficulty of giving frequent doses of tablets.

Literature and further information on request from Medical Dept.

BOOTS PURE DRUG COMPANY LIMITED
NOTTINGHAM, ENGLAND

S40

Viscopaste and Ichthopaste Bandages

Viscopaste and Ichthopaste bandages are recommended as an alternative to elastic adhesive bandaging, in the treatment of chronic varicose and eczematous conditions and where the patient's skin is hyper-sensitive. Both bandages have non-fray edges and are thoroughly impregnated with zinc oxide

gelatin paste of the Unna type. Ichthopaste contains, in addition, 2% Ichthyol.

Available in 6 yd. lengths by 3½" wide.

Descriptive literature may be obtained on request to the Medical Department of the Manufacturers.

VISCOPASTE & ICHTHOPASTE Bandages are made in England by T. J. Smith & Nephew Ltd., Hull

THIS IS THE CENTANÆST

It presents all the features of the Combined Boyles and C.M. Absorber in a convenient form. The Centanæst is clean. All gas conduits are enclosed; the room is easily visible and fully protected. The Absorber can be safely housed when not in use. Cylinders are readily accessible and easily changed. The cabinet is provided with drawer and table space. The British Oxygen Company Ltd. is proud to put the Centanæst at the service of the Medical Profession.

BOYLES APPARATUS The introduction of the "Centanæst" will not eliminate from our range of apparatus the universally known Boyles Table. Our Model "G" with the Coxeter-Mushin Absorber presents a combined apparatus for the administration of "open" or "closed circuit" anaesthesia.

THE BRITISH OXYGEN COMPANY LTD

For promoting Natural Restful Sleep

THE control of insomnia presents a problem that often cannot be effectively or safely solved by recourse to the use of hypnotic drugs.

"Ovaltine" provides a safe and natural means of inducing sleep in many cases, especially where the basis of the insomnia is digestive unrest, nocturnal hunger or nervous instability. Taken before retiring, it promotes quiet and restful sleep by reason of its gentle sedative effect on the nervous system and its faculty of assisting digestive ease.

"Ovaltine" is a natural food prepared from milk, eggs, malt extract, cocoa and soya. It is possessed of a truly delightful taste and is appreciated by every type of patient.

the province of the local health authorities than to that of general practice. To learn that I share the views of such well-known paediatricians is indeed encouraging.—I am, etc.,

London, W.6.

B. ROSEFIELD.

Routine Medical Examinations

SIR,—I read with interest Dr. M. E. M. Herford's admirable letter (May 14, p. 870) entitled "Routine Medical Examinations." He has not mentioned one use of the examination with regard to prospective employees which is, I consider, of great importance. It is that the examination, when accompanied by a full health history of the applicant, enables a Pulheems system to be used. This system may be either that used in the Army (see the *Journal* of Jan. 15, p. 83) or one which the industrial medical officer has compiled as specially applicable to the industry with which he is concerned.

It is then possible to make a recommendation to the personnel department with regard to the job (or jobs) which the applicant is fitted best to fill. This ensures the most economical use of the man's labour, and guards him against any industrial hazard which might be specially dangerous to him in view of any departure from the normal in his physical or mental state.—I am, etc.,

London, S.W.7.

R. FRANK GUYMER.

Death Following Neostigmine

SIR,—Just before reading Professor R. R. Macintosh's note (May 14, p. 852) on death following injection of neostigmine, sudden death occurred under very similar circumstances, on the operating table, in a patient whom I was anaesthetizing.

A deeply jaundiced woman of 62 was being operated on for the relief of common bile-duct obstruction. The anaesthesia was "kemithal" 1 g., *d*-tubocurarine 25 mg. in divided doses, and 50% nitrous oxide and oxygen. Assisted respiration was maintained throughout.

There were a few cardiac irregularities during the operation, which lasted about 60 minutes, but otherwise nothing of note. Some cyclopropane was given at the end of the operation to afford complete relaxation for the sewing up of the peritoneum. The patient's condition was satisfactory.

When this was finished 2 mg. of neostigmine mixed with 1/100 gr. (0.65 mg.) of atropine was injected intravenously. A short while after this the patient quite suddenly became grey and pulseless. The abdomen was reopened very rapidly and cardiac massage was performed, together with the usual remedial measures. No response whatever was obtained.

At necropsy the operation area was perfect, and the only finding was said to be a very poor myocardium.

This, of course, was highly unsatisfactory and disturbing from the anaesthetist's point of view, and in view of Professor Macintosh's case I feel this should be published as a possible further example of death caused by the rapid injection of neostigmine.

I have made a practice, since hearing of Professor Macintosh's case, of giving the neostigmine and atropine in very small divided doses. It might also be remarked that we have found that slowing of the pulse occurs much less commonly if the proportion of atropine to neostigmine is that of 1/100 gr. (0.65 mg.) to 2 mg.—I am, etc.,

Lincoln.

J. CLUTTON-BROCK.

Research in Renal Disease

SIR,—Dr. A. A. Osman (May 21, p. 910) has drawn attention to a number of matters which far transcend in general importance the particular one which prompted him to write to you—hence this present note. We ourselves stress, as he has done, the leading role played by renal disorders in the incidence of crippling disease and of death; we also think, as he obviously does, that there should be far fuller integration of knowledge about the kidney, more systematic planning and co-ordination of research to add to that knowledge, and expert transmission of the results in the ways best calculated to ensure that renal irregularity is recognized and, if possible, checked before irreversible changes have occurred.

These objectives demand co-operation between a wide variety of preclinical, clinical, and other workers, very much more generous endowment than has hitherto been available, and one

or more research and teaching headquarters. From the experience of two of us at Oxford during 1945–7, and of the three of us in London from early in 1948 to date, we can testify whole-heartedly to the value of the many-sided approach to renal problems. The story of the Oxford co-operative effort is well enough known; and we need not give it again here. In the current renal researches our own main contributions are necessarily those of a physiologist, a comparative physiologist, and an orthopaedic surgeon, and we are very conscious of the widening of our scope which association with other workers—pathologists, obstetricians, renal-clearance experts, and so forth—is making possible.

Because of our experience on a small scale with relatively scanty research time and financial support, we can envisage the sort of success which could attend the efforts of a far wider association of researchers with fuller time, proper accommodation, adequate endowment, and centralized direction. In the same building or buildings, as a correct counterpart to all this, the knowledge secured by past and current research could be made available in clear-cut form to postgraduates and students, and they could be briefed in the best methods for the prevention and arrest of kidney malfunctioning.

Is it too much to hope that the necessary steps will before long be taken, and that some more radical kind of halt will thereby be called to the disablement and fatalities produced by renal disorders? There are many institutes of cardiology but few, if any, of nephrology, though the heart is more often than not the victim of the kidney's initial malpractice.—We are, etc.,

Hereditary Cheiropompholyx

SIR,—The case seen by Dr. S. H. Curry (May 21, p. 913) appears to be the local variety of epidermolysis bullosa more or less completely localized to the hands or feet or both hands and feet, characterized by a recurrent bullous eruption in summer—the exciting cause being the hot weather more than local trauma.

The familial incidence was first pointed out by E. A. Cockayne,¹ who could find only one similar case previously recorded,² and that without known family incidence. This was in a boy, then aged 4 years, under my care, who, I hear, suffered very much from the complaint in summer when he was in the Royal Air Force during the late war. I have been told of a similar case in a boy aged 6 years, but with hereditary incidence. Many cases have been recorded in America—see especially Waisman's³ report entitled "Recurrent Bullous Eruption of the Feet and Hands (Weber-Cockayne)." The striking pedigree given by J. B. S. Haldane⁴ should also be seen.—I am, etc.,

London, W 1

POINTS FROM LETTERS

Treatment of Spondylitis with Cortical Extract

Dr. J. THOMSON SHIRLAW (Wigan) writes: After reading the leading article (May 7, p. 812) I am constrained to mention a case of ankylosing spondylitis treated by me last year with an extract of suprarenal cortex. The patient's own statement of its effects is that, whereas his symptoms were aggravated by previous injections of gold and the application of x rays, they were improved after the adrenal cortex injections. I was led to adopt this treatment by the appearance in him of thick, solid limbs, shoulders, and buttocks, loss of sexual desire, and exhaustion after little effort. Owing to the high cost of the remedy I gave 40 minims (2.4 ml.) twice weekly; as he improved I reduced this to once weekly. Such doses were too small and too widely spaced. Now, encouraged by the results of the clinical trials mentioned in your leading article, I hope to resume the treatment and will make it more intensive. There is little doubt that in my case, at any rate, there is a break in the harmonious relations of the functions of the pituitary and adrenal glands.

Medical Notes in Parliament

NATIONAL HEALTH SERVICE (AMENDMENT) BILL

The National Health Service (Amendment) Bill was given a second reading in the House of Commons on May 24.

The Lord Advocate, Mr. JOHN WHEATLEY, said the purposes of the Bill were broadly three. First, to clarify and amend the application to partnerships of those sections of the National Health Service Acts which prohibited the sale of practices by doctors in the Service and which compensated them for the resulting loss of the selling value of the goodwill. Secondly, to carry out certain promises of amendment made to the medical profession in the discussions both before and since the beginning of the Service. Thirdly, to make certain minor administrative changes which experience had shown were desirable.

Mr. Wheatley then described in detail the effect on medical partnerships of Part I of the Bill, which was printed in full in the Supplement of May 21 (p. 274). There were only 50 "mixed practices," of which only one was in Scotland, and the new fund required for compensation in these cases was not likely to be large. He drew attention to the opportunity given to all members of partnerships who had not yet joined the Service to do so before the second appointed day, which would be two months after the date on which the Amending Bill became an Act. The committee under the chairmanship of Mr. Justice Slade had recommended that assistants should be treated in the same way as partners, and effect had been given to this recommendation.

It was realized that, despite all the attempts which had been made to secure justice as between one party and another, there might be the odd case in which the operation of the principles laid down by the Slade Committee and incorporated in the Bill might lead to hardship. Provision had therefore been made for arbitration in such cases, and, failing agreement between the parties on a single arbitrator, the issue would be referred to a committee consisting of a legal chairman appointed by the Lord Chancellor or the Lord President of the Court of Session, a medical practitioner appointed by the President of the British Medical Association, and an accountant. Finally, in Part I of the Bill it was made clear that Section 35 of the principal Act, or Section 36 of the corresponding Act in Scotland, did not prevent a doctor who had never been in the Service from selling the goodwill of his practice even although part of that goodwill was acquired from a partner inside the Service.

It was possible under the Health Service Acts, and in point of fact under the National Health Insurance Acts ever since 1912, to introduce by regulation a whole-time salaried service. The pledge given by the Minister of Health that it would be made clear in legislation that a full-time service could not be instituted by regulation alone was fulfilled in relation to general practitioners by Clause 10 and in relation to specialists by Clause 11 of the Bill.

Among other minor matters which arose under Part II of the Bill professional members of the tribunal were to be drawn from a standing panel of members of the profession selected to cover the different types of practice involved, whether rural, industrial, or some other type. All executive councils were in future to elect their own chairman from among their own members. Provision was made for the removal from the lists of executive councils of doctors or others who had removed from the district and were not, in fact, available for that or any other reason to provide services in that area. The period for claiming fees under the Midwives' Act was extended from two months to three months.

Under Clause 12 they had put the coping stone on the structure of Whitley Councils built up for the negotiation of the terms and conditions of service of all of the many types of officers engaged in the National Health Service by enabling arbitration machinery to be set up where disagreement arose between the official and the staff sides. The intention was to set up a tribunal for the Health Service on the lines of the Civil Service Arbitration Tribunal, the details of its constitution and procedure to be settled by the terms of an arbitration agreement made between the two sides. He was confident that the Bill would receive support from all sides of the House. It was but a further step in the development of a scheme which, in its short span of ten months, had already invoked the admiration and respect not only of the people of this country but of the people of the whole world.

Buying and Selling Goodwill

Sir HUGH LUCAS-TOOTH said he did not feel strongly about the retention or otherwise of the power of a doctor to sell the goodwill of his practice. This was not really a question of

principle in his view—a view generally shared by the Opposition. The members of some professions had been able at all times to sell and to buy the goodwill of their practices. The members of other professions had not been so able. That applied, for example, to the legal profession, and he thought that it was a pity that there had not been the same state of affairs in the medical profession. He recapitulated the criticisms of Sections 35 and 36 of the principal Act put forward by Mr. Willink in the committee stage and on report. It was a pity the Minister of Health had not consulted with the law officers on these points at the time they were discussed.

After the principal Act was passed lengthy discussions took place between the Minister and the doctors. The doctors had three main objections to coming into the new Service: the fear of a full-time salaried service; their objection to the abolition of buying and selling of practices; and their fear of direction. The doctors had quite properly and democratically held a plebiscite at which general practitioners voted by an overwhelming majority of the order of 12 to 1 against coming into the scheme. The doctors meant business, and the Minister had had to give way. On every principal objection which the doctors raised the Minister had had to give way.

Subject to detailed consideration in committee the Opposition thought this was a good Bill and they desired to give it their support. Clause 10 said: "The remuneration to be paid . . . shall not . . . consist wholly or mainly of a fixed salary." He thought that effect would be given to those words if the fixed or basic salary did not exceed half the total emoluments.

Concluding, he said that the fundamental trouble with the Health Service Acts was that the choice of priorities was wrong. The Acts were founded on two fallacies: that unlimited money would be available, and that only expenditure was needed to provide a good health service. Free spectacles were admirable things, but were very rarely matters of life. The more free spectacles were available to the people the longer the queues would become at the hospitals. The hospitals were matters of life in this connexion.

Mr. BEVAN, intervening, said that it was perfectly competent for the Opposition to put down an amendment to the Bill removing from the range of free issues any part of the Health Service. If they wished to do that they should take the opportunity. If the Opposition wished to restrict the range of free health treatment it was quite open to them to put down an amendment.

Mr. FRANK BYERS said that the question of the direction of doctors had been used as a sort of political propaganda stunt. The National Health Service was a long-term project and he deplored irresponsible political sniping at the Health Service and at the Government in their administration of it. He thought that there were many things that would have to be amended. The position of the rural doctor would have to be looked at again. The Bill ought to have been called the National Health Service (Amendment No. 1) Bill, because there would have to be amending Bills Nos. 2, 3, and 4, and then a consolidating Bill.

Specialist Services

Mr. MESSER thought that the Minister in this Bill had given the doctors more than most people would consider necessary. Discussing specialist services, he said that part-time specialist services were tied up with the paid beds provision. Children who required tonsillectomy might have to wait for nine months to two years for the operation but could be admitted to hospital at once if the operation were done privately at a cost of from £30 to £50. That was one of the dangers of part-time specialists.

The part-timer could undertake work which entitled him to 94/11ths of the salary he would earn as a full-time specialist. He was entitled to up to 800 guineas per annum for domiciliary visits. He could make special visits on behalf of the regional board at 5 guineas per visit. He could work as a locum tenent at 5 guineas per half-day, and he was entitled to work in his own private practice. There were also such things as income tax allowances for expenses that were denied the full-time specialist.

He mentioned these things because he thought too much importance was being placed on the proviso that in no circumstances would there be introduced a regulation which would make all specialists full-time. Mr. Messer went on to suggest that consideration might be given to placing on the regional hospital boards the responsibility for the provision of facilities for postgraduate study.

Mr. PETER THORNEYCROFT criticized not so much what was in the Bill as what was left out. On the question of analgesia in childbirth he had a proposition to put to the Minister of Health. Two new Clauses had been placed on the Order Paper, and if the Minister would accept them on the committee stage he would withdraw his Analgesia in Childbirth Bill. Those new Clauses gave him 75% of what he wanted.

Mr DAVID RENTON, speaking as the son of a general practitioner, took objection to the vagueness of Clause 10. It would be useful if the Minister were to give the House some idea of what he had in mind when he said that in special circumstances the proviso with regard to there being no fixed salary or not mainly a fixed salary should not prevail. If these 'special circumstances' were to be interpreted too broadly the whole effect of this amendment would go by the board.

The Minister and the Medical Profession

Dr BROUGHTON welcomed the Bill but he also thought that the Minister had gone too far in trying to meet the demands of the medical profession. He quoted extracts from a leading article in the *British Medical Journal* of May 21 (p 904): "The B.M.A. conducted a campaign against the introduction of a whole-time salaried medical service." "It did not accept the assurance of the Minister that this was not the Government's intention." "Mr Bevan once more bowed before the storm."

The Act of 1946 was arranged so that the Minister could conform to the wishes of the medical profession and the best interests of the country. The day might come when the profession wanted a full-time medical service, and it would have difficulty in obtaining one if Clause 10 became law. He suggested that the Minister was pampering a section of the profession most politically prejudiced and panic-stricken. He quoted again from the same *B.M.J.* leading article.

The only other criticism he made was in regard to the proposal that the executive councils should allot to the medical, dental, and other local committees such sums for deferring the administrative expenses, including travelling and subsistence, as were necessary. Why should the administrative expenses of these committees and the travelling and subsistence allowances of the members have to be met by compulsory deductions from the salaries of doctors, dentists, and pharmacists? This should be a public expense. Doctors were not wealthy men, and they must not be judged by their gross incomes because many of them had heavy practice expenses. They asked only that their remuneration should be sufficient to allow them to give freely their self-sacrificing service in accordance with the traditions of an honourable profession.

Mr BAIRD said he was astonished to hear Mr Renton deploring the fact that the National Health Service Act had been treated as a political issue. The Health Service scheme had been political right from the very beginning and up and down the country, before the Bill was introduced the Tory Party and the B.M.A. were misrepresenting what was in the minds of Labour members. He referred especially to the dental services under the NHS. It was written into the original Act of 1946 that the Minister should provide a priority service for expectant mothers and young children, but the fact was that the establishment of dentists employed by local authorities for this purpose for treating the priority classes was under 50%. The Minister should take over the treatment of these priority classes and run it on a regional basis. There were perhaps 10% of the dentists who were guilty of acting in a most unprofessional manner.

Conciliation Machinery

Mr LINSTED said it was hopeless to think of attracting dentists into a salaried service while there was the enormous disparity between official salaries and what could be earned in private practice. The Minister's main task now was to carry the professions with him. He had gone some way to meet the doubts of the medical practitioners, and it was of value to have a statutory guarantee that a full-time salaried service should not be introduced save by Act of Parliament. He thought that some gesture to the dentists was very badly needed. The dentists felt that they were faced with a unilateral alteration of terms of service by regulation.

He felt that Clause 12 should be carefully considered because it brought into the NHS a large section of the conciliation machinery applied to industrial disputes. This raised two important points of principle. First, the Minister of Labour was brought in under the Conciliation Act and as a matter of constitutional propriety he wondered whether it was right or proper for one Minister to purport to arbitrate in a dispute where one of the parties was a Minister of the Crown. This wanted looking into on the committee stage to ensure that they were not putting either the Minister of Health or the Minister of Labour into a false position.

The second and more important point was that if the industrial court was chosen under the Industrial Courts Act, 1919, as a means for resolving a dispute between the Minister and any section of employees in the National Health Service then there was no provision for the enforcement of any award which might be made. He hoped the Minister would be able to give some assurance that in these arbitration proceedings,

whatever form they took, he would as party to them regard himself as bound in advance by the decision of the arbitrator.

Mrs MANN referred again to the question of analgesia under the Midwifery Service, and quoted freely from the report of a subcommittee of the Medical Women's Federation which appeared in the opening pages of the *British Medical Journal* of Feb 26 (p 333).

Mr HOWARD welcomed the amendment to the Bill allowing hospital boards and management committees to subscribe to certain approved associations. He hoped that the right accorded to certain committees to elect their own chairmen would be extended. He asked the Minister to explain the significance of another minor amendment the removal of the words 'loss of remunerative time' and their substitution by 'any loss of earnings which would otherwise be made.' Was this amendment significant, sinister, or merely silly?

He also made the point that in some of the Acts recently imposed by the Minister the question of war damage had been treated unfairly. One hospital had put in its original budget provision for capital expenditure which included £100,000 of war damage. That item had now to be cut to £90,000. Therefore the board of that hospital must leave a vast amount of war damage unrepaired for yet another year. This difficulty applied to every hospital in every blitzed area. In conclusion, he urged the Minister to carry out his declared intention of delegating responsibility as widely as he possibly could. Without such delegation the Service could not possibly work satisfactorily.

Safer Motherhood

Dr HADEN GUEST said it had been contemplated from the beginning that it would be necessary to introduce not only one but a series of amending Bills. There were two simple and important things that had been done since the NHS came into operation. Women and children who had previously had to pay for medical treatment were now able to get treatment without paying fees at all. The other great gain was in the reorganization of the hospital system.

He thought that some Members were inclined to attach too much importance to the question of analgesia in childbirth. It was desirable that women should be relieved of the pain of childbirth, but that was by no means the only thing of value about a properly organized maternity service. Analgesia was not necessarily wanted for all women but safer motherhood was.

They wanted to reduce to nil the number of deaths in childbirth and the number of cases of injury to mother or child at the time of birth. This could be done. He referred to a series of 5,000 consecutive deliveries without a maternal death reported recently by Mr Norman Emblin in the *British Medical Journal* of Feb 12 (p 260). These results had been achieved not by anaesthetics or analgesics only, but by the setting up of an organization which meant that every difficult case had a doctor and a medical and surgical specialist team in attendance.

He pointed out, however, that a great increase in the use of analgesia had been brought about by administrative methods under the National Health Service. In 1938 the proportion of women who received analgesia in childbirth was only 0.4%. By 1943 it was 1.2%, and by 1945 3%. The 1946 figure was 6.9%. By 1947 it was 13.3%, and in the last six months of 1948 the figure had gone up to 35%. He thought that this was one of the advantages that had flowed from the NHS. It was not true to suggest that the Ministry of Health was failing in its duty in this respect.

Colonel STODDART SCOTT thought the Bill improved the original Act, but he hoped that hospital management committees and governing bodies of teaching hospitals would also be able to choose their own chairman. He referred to the fact that before July 5, 1948, it was obligatory upon local authorities to provide accommodation for the aged sick. The 1946 Act took this responsibility away from the local authorities and put it into the hands of the regional hospital boards. He did not believe that the boards had carried out these duties in the same way as they were carried out before.

When people were old and a little muddled it was found that the only hospital accommodation available to them was in a mental hospital. At one Birmingham hospital in 1947-8 only 20 people over the age of 65 were admitted. In the period of 1948-9 the figure was 93 and of these old men and women 30 had died from pneumonia, heart trouble, and similar conditions. It was difficult to get old people who were chronically ill into other accommodation such as previously existed.

In the NHS the first priority must be an adequate hospital service. It was remarkable that a drastic cut imposed on the Health Service by the Minister should have been on that element of the Service which had borne the brunt of increasing attendance. At some general hospitals in the North out-patient attendances had increased by 100%. He thought it more important that hospital accommodation should be available than that

people should be able to obtain two pairs of identical spectacles, or that wigs should be given to foreigners.

Drugs for Private Patients

Mr. HENRY STRAUSS welcomed the Bill and so did Sir WAVELL WAKEFIELD, who said that there was one matter which he had raised previously at question time. When the Service was introduced the Minister stated that people would be free to have the Service in whole or in part. Members of the public who wished to pay for the services of a doctor and therefore did not use that part of the Service felt a great grievance because they were debarred from having the free appliances or drugs available to patients who took advantage of the whole Service.

It was wrong that because a person elected to be a private patient he should be debarred from the benefits that the Minister had stated very definitely would be available to him. Many doctors while in the State service had private patients. In treating State patients doctors could not prescribe appliances or drugs which were not acceptable to the State. Surely the same set of rules and the same administrative requirements could be applied to the person who was a private fee-paying patient.

Foreigners who made no contribution received the service free of charge. Private patients could not receive drugs and appliances which they had paid for by way of taxes. The Minister ought to remove this grievance and make it possible for people to receive drugs though paying fees for private treatment from doctors. He also suggested that whatever expense there would have been to the State ought to be allowed for in any charges made for private paying-beds.

Lieut.-Colonel WALTER ELLIOT said that there were now about 454,000 hospital beds in the country. The Emergency Medical Service had run this number up to well over half a million, and so long as there were 50,000 hospital beds in existence but not staffed all the steps which could be taken towards solving the problem of producing an adequate Health Service had not been taken.

There had been considerable uneasiness and distress among the medical profession. There was still a deep Freudian bruise in the mind of the medical profession about the negotiations, which were conducted more as a military operation than as a kind of negotiation. However, the Bill before them carried out the promise of the Minister, and he did not think there was any breach of faith in the Bill.

Dr. Broughton, he said, had early acquired the political trick of using that part of a quotation which suited him and leaving out the rest. He had quoted from the *British Medical Journal* leader to the effect that they had refused to accept the assurances of the Minister. He had left out the explanation in the second half of the sentence, which was that although the Minister might not remain he could not bind his successor. He might perhaps have quoted also another leader in the *British Medical Journal* (May 14, p. 856) dealing with the actual reduction in beds which would follow the recent circular from the Minister.

He quoted at length from this leading article on the effect of the recent cuts on St. Bartholomew's Hospital, Oxford, Bristol, Birmingham, and Manchester. The cost of the health services was still rising and had not yet reached its peak. The Opposition did not propose any cuts in the health services; the money to complete them would have to be found. The Bill before them certainly implemented the promises made by the Minister during the passage of the Bill, promises which the Opposition believed to be necessary. If they had not been implemented then it would have given rise to a grave breach of faith.

The Minister's Reply

Mr. BEVAN said that most of the doubt which arose in 1946 and subsequently and most of the anxieties which the doctors had been suffering were a direct consequence of the unbridled propaganda of some leaders of the medical profession at that time. They created suspicion and doubt where none in fact existed. The Amending Bill was necessary not because of the obscurity of the original Act but because of the complexity of the subject. At the same time, although there were between 17,000 and 18,000 G.P.s in the country, this Bill affected only 50 partnerships.

The proposed new Clauses about analgesia he would deal with at the committee stage. He could certainly not accept the peculiar bargain of agreeing to admit those Clauses in return for the withdrawal of a Private Member's Bill that might never reach the Statute Book. The country was being given the impression that if only these new Clauses were in operation more women would be relieved of pain in childbirth. This was not true. They were up against the physical limitations of the lack of sufficient trained midwives and general facilities.

Every sick person must feel that he or she was receiving as much attention as any other person. It was wrong to suggest that a certain group of patients were to have priority over any

other group. Before many years had passed every woman in this country would be able to have analgesia or anaesthesia if she wanted it.

The Minister then went on to discuss the question of expenditure. One member had asked, "Why on earth should we cut the hospital service and issue free spectacles?" By what conceivable alchemy could he transmute a citizen without a pair of spectacles into a trained nurse looking after a patient? He could not get trained nurses by letting half the country go blind. If the Opposition wished to economize at the expense of the provision of one of the free services let them have the courage to put down an amendment.

The administrative expenses of the National Health Service Act worked out at 2.3% of the total cost. The administrative expenses of private insurance companies were anything from 9½ to 40%. This 2.3% total included the Health Division of the Ministry of Health, the price-fixing machinery for the pharmaceutical services, the Dental Estimates Board, all the executive councils, all the regional hospital boards, and all the management committees and secretarial expenses.

Administrative expenditure should be scrutinized narrowly, but there were no great savings to be obtained on the administrative side. The financial cuts were an attempt by the central administration progressively to exercise financial discipline over the whole Service while at the same time leaving the utmost amount of independent action at the periphery.

To the extent that abuses existed in the Health Service, to the extent that there were faults, they arose directly from those parts of the Health Service that had to be articulated through private enterprise—opticians, dentists, chemists, but not so much the chemists. He believed that before long everybody would take pride in the Health Service. It was already an inspiration to other nations.

The Bill was read a second time and committed to a Standing Committee, and the Money Resolution was agreed to in Committee.

Overcrowding in Mental Hospitals

On May 19 Mr. SORENSEN asked to what extent mental hospitals in London and the Home Counties were overcrowded; approximately what proportion of beds and wards was not being used through lack of staff; and whether recruitment for the mental hospital services was progressing or not.

Mr. BEVAN answered that accommodation in use was overcrowded by 4,048 beds (approximately 11% of the total). The proportion of bedspace available but not used because of lack of staff was 4.1%. Separate figures for wards not in use for this reason were not available. Recruitment of nurses was progressing. In 1948 there were 15% more nurses employed in these hospitals than in 1945.

Artificial Limbs

Answering Lord WILLOUGHBY DE ERESBY, Mr. MARQUAND stated on May 24 that about 50 patients had worn artificial legs fitted with suction sockets for periods ranging up to about two years. As a result of observations made during these trials a number of modifications had been made, especially in the valve. A supply of the improved valves had just been received. He intended to ask a number of limb-makers throughout the country to fit suction sockets to their particular make of legs for trial by not less than another 100 patients.

Mr. Marquand further said that six mechanical hands of one type had undergone trials by selected amputees since April of last year. Reports were available for consideration by the Standing Advisory Committee on Artificial Limbs at their next meeting. Another type of mechanical hand had been produced and was being tested. If the Standing Advisory Committee was satisfied with the performance of either or both of these types of mechanical hand they would be made available to all disabled war pensioners and National Health Service patients for whom they were suitable.

Administrative Staff.—Mr. MCFARLANE inquired on May 17 what was the number of persons engaged on hospital administration in Scotland on July 1, 1948; and the number at present engaged. Mr. WOODBURN replied that information on the number at July 1, 1948, would have to be obtained specially and he did not feel justified in asking hospital authorities for it. The present number of officers engaged in administration (including clerical and typing staff) was about 2,200, which comprised the staffs of the five regional boards, the 84 boards of management, and the 425 hospitals in the Service.

Dental Services.—There were 9,347 dentists on the dental lists in England and Wales on May 1. The Ministry of Health Estimates, Class V(2), provide £28,204,000 for the cost of the general dental services in England and Wales.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 14

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland
Figures of Births and Deaths, and of Deaths recorded under each infectious disease, for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire (e) The 10 principal towns in Northern Ireland
 A dash — denotes no cases; a blank space denotes disease not notifiable or no return available

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

|| Includes puerperal fever for England and Wales, Eire, and Northern Ireland.

EPIDEMIOLOGICAL NOTES

Analysis of Deaths in 1947

The Medical Tables of the Registrar-General's Statistical Review for 1947 record that 515,591 civilians died in England and Wales during that year, an increase of 26,537 over 1946. This gave a crude death rate of 12.3 per 1,000 civilian population, compared with 12.0 in 1946 and an average rate of 12.1 for the 10 years 1929-38. Of these deaths 144,570 were due to heart diseases and 77,649 to cancer. These two groups thus accounted for 28.0%, and 15.1% of the total respectively; in 1938 these proportions were 24.3%, and 13.9%.

Deaths due to diseases of the coronary arteries and angina pectoris showed an abnormal increase, numbering 33,168 in 1947, compared with 28,580 in 1946 and 15,409 in 1938. To get a true comparison between those two years it is necessary to discount the changes in the sex and age structure of the population. When this is done, taking the 1938 incidence as 1,000, the corresponding figures in 1947 are 1,851 for men and 1,765 for women, indicating a total increase of about 80% in mortality attributed to this cause over the nine years.

Deaths from cancer show that male mortality is still increasing, and that the halt in the decline of female mortality seen in 1946 has been maintained. While for cancer of some sites, such as the mouth and pharynx, mortality is falling for both sexes, the mortality from cancer of other sites shows great increases. Among the 77,649 deaths in this group cancer of the lung contributed 9,535 (7,805 men and 1,730 women), compared with 4,658 (3,609 men and 1,049 women) in 1938. This accounts for three-fifths of the increase in male deaths from cancer.

Deaths from appendicitis numbered 1,491, less than half the total recorded in 1938, when there were 3,027.

Food Poisoning

The Ministry of Health memorandum on food poisoning (188/Med) was issued in 1935. Since then there have been two important developments in connexion with the control of disease conveyed by food—namely, the notification of food poisoning under Section 17 of the Food and Drugs Act, 1938, and, more recently, the establishment of the Public Health Laboratory Service. The memorandum has therefore been revised and issued to all medical officers of health.

Section 17 (1) of the Food and Drugs Act, 1938, provides that if a medical practitioner suspects that a patient is suffering from food poisoning he shall send to the medical officer of health a certificate stating (a) the name, age, and sex of the patient, and the address, and (b) particulars of the food poisoning.

The main object of Section 17 is to ensure that the M.O.H. is informed of outbreaks of illness occurring in his district and believed to have been caused by food. Although food poisoning is not defined in the Act of 1938, the Minister does not think that notifications under Section 17 need include cases in which food causes an infectious disease which is otherwise statutorily notifiable as such. In practice this has not happened except on occasions when cases of illness clinically and epidemiologically indistinguishable from food poisoning have been so notified but have proved on investigation to be cases of bacillary dysentery. This is unavoidable, and in general the experience of the last 10 years has shown that the notification of food poisoning has achieved the purpose intended—namely, that circumstances requiring further investigation and action of a kind which a general practitioner cannot be expected to undertake are brought promptly to the notice of the local M.O.H., who can then enlist the help of the Public Health Laboratory Service.

The Registrar-General has requested medical officers of health from the beginning of 1949 to include the notified cases of food poisoning in their weekly returns and also to make a quarterly return of the total of such cases amended by reason of corrected diagnoses. The publication of these figures at regular intervals by the Registrar-General may help to bring to light hitherto unrecognized factors in the causation of food-borne disease.

Discussion of Table

In England and Wales a decrease was recorded in the notifications of measles 854, whooping-cough 147, acute pneumonia 88, and typhoid fever 30. There was an increase in the incidence of scarlet fever 95, cerebrospinal fever 23, and dysentery 18.

A fall in the incidence of measles was reported in most areas; the largest falls in notifications were Southampton 116 and Middlesex 100. The only notable exception to this general trend was a rise of 190 in Kent.

A small rise in the incidence of scarlet fever occurred in the South and North and a slight fall in the Midlands; the only large variation in local returns was an increase of 43 in Lancashire.

There were small variations in the notifications of whooping-cough, the largest being a decrease of 91 in the total for the south-west counties.

The largest outbreaks of dysentery were Lancashire 30 (Oldham C.B. 27) and Yorkshire West Riding 15 (Sedburgh R.D. 10). The next largest return was Cornwall, Bodmin M.B. 7.

In *Scotland* there was an increase of 51 in the notifications of scarlet fever, and decreases were recorded for whooping-cough 21 and measles 16. The rise in the incidence of scarlet fever was confined to the western area. Notifications of dysentery in Glasgow increased from 14 to 25.

In *Eire* there were decreases in the notifications of measles 14, scarlet fever 12, and diarrhoea and enteritis 9. In Dublin C.B. an increase of 26 was recorded in the notifications of measles.

In *Northern Ireland* an increase of 33 in the notifications of measles was the chief feature of the returns. The incidence of measles increased in County Tyrone 30, Belfast C.B. 20, and County Antrim 10; in the remaining areas a decrease was reported.

Quarterly Return for Eire

During the December quarter of 1948 the birth rate was 20.0 per 1,000, which was 0.3 below the rate for the fourth quarter of 1947. The infant mortality rate was 48 per 1,000 registered births, being 17 below the rate for the preceding December quarter. The general death rate was 11.4 per 1,000 and was 0.2 below the rate for the preceding fourth quarter.

For the whole year the birth rate was 21.9 per 1,000 and was 1.3 below the rate for 1947. The infant mortality rate was 49 per 1,000 registered births and was the lowest rate ever recorded. The general death rate was 12.2 per 1,000, and this also was the lowest ever recorded.

The death rate from tuberculosis was the lowest on record. Deaths from pulmonary tuberculosis numbered 2,398, and from other forms of tuberculosis 619; these figures were 433 and 250 respectively below the totals for 1947. Deaths attributed to the principal epidemic diseases numbered 651 and included 340 from diarrhoea and enteritis in infants under 2 years (80 in Dublin C.B.); 196 from whooping-cough; 61 from measles, 31 from diphtheria; and 14 from typhoid fever.

Week Ending May 21

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,008, whooping-cough 2,824, diphtheria 92, measles 8,478, acute pneumonia 441, cerebrospinal fever 34, acute poliomyelitis 11, dysentery 55, smallpox 6, paratyphoid 8, and typhoid 4.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

In Congregation on May 28 the honorary degree of D.Sc. was conferred on Viscount Addison, K.G., P.C., M.D., F.R.C.S., Lord Privy Seal and Chairman of the Medical Research Council; Professor C. F. Cori, professor of biochemistry in the Washington University School of Medicine; Sir Charles Harrington, Ph.D., F.R.S., Director of the National Institute for Medical Research; Kaj Linderstrom-Lang, Director of the Carlsberg Laboratory, Copenhagen; Professor A. W. K. Tiselius, professor of biochemistry in the Royal University of Uppsala; and Professor Jacques Tréfouel, Director of the Institut Pasteur.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examination indicated.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—R. Buri, J. A. Byrne, H. A. Charlton, M. G. Corcoran, F. J. Fleischer-Djoletto, W. J. Foote, J. Gemmell (hon. recommended for the Milne Medal in Tropical Medicine), J. Haworth, J. C. V. Murphy, W. L. Palmer, D. Paukan, G. Pringle, K. L. Stuart (recommended for Warneford-Yorke Medal in Tropical Hygiene), S. W. Thomson, R. C. Troup.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council held on May 20 the following appointments to part-time posts were made: *Lecturer in Social and Industrial Medicine*, Dr. James Sharpe; *Clinical Teacher in Obstetrics and Gynaecology*, Mr. David H. Lees; *Clinical Teacher in Surgery*, Mr. R. B. Zachary.

Dr. J. H. Bowie (Lecturer in Bacteriology); Dr. J. M. G. S. (Lecturer in Medical Pathology); Dr. T. Stapleton (Lecturer in Public Health); and Dr. Joan Laird (Research Assistant in the Department of Medicine).

Medical News

Association of Scientific Workers

Lord Boyd-Orr has been elected president of the Association of Scientific Workers.

Scholarships in Norway

The Norwegian Government is offering two scholarships to British university graduates or students intending to graduate this year. A knowledge of Norwegian is desirable though not essential. The scholarships are tenable for the academic year Sept. 1, 1949, to June 15, 1950. Applications should be sent before June 13 to the Controller, Education Division, The British Council, 3, Hanover Street, London, W.1.

Visit of Italian Pathologist

Professor Guido Vernoni, Director of the Rome Institute of General Pathology and Professor of Pathology in the University of Rome, is spending a fortnight in Britain under the auspices of the British Council visiting pathology and biochemistry laboratories. He lectured on "The Pathogenesis of Cancer" at the Chester Beatty Research Institute on May 23 and on "The Pathogenesis of Fevers" at the Royal Society of Medicine on May 24.

Memorial to Army Nurses

Field-Marshal Sir William Slim, C.I.G.S., unveiled on May 28 at the Queen Alexandra's Military Hospital, Millbank, a memorial plaque to the nurses of Queen Alexandra's Royal Army Nursing Corps who lost their lives during the war of 1939-45.

International Health Control

The Public Health Committee of the Brussels Treaty Permanent Commission has simplified the health control measures for those travelling by sea or air between Britain, France, Belgium, Holland, and Luxembourg. Each country will inform the others of all diseases notifiable in its territory, and provide a list of its main seaports and airports, the names, addresses, and telephone numbers of the medical officers in charge, and details of the sanitary equipment at each port. The countries will adopt a uniform type of warning postcard on which passengers landing in an "infected" area or from a "suspected" ship state the address to which they are going.

The Centenary of the Brompton Hospital

It is hoped to hold a dinner in November of this year to celebrate the centenary of the Brompton Hospital. All those who have been on the medical staff or residents of the hospital who would like to be present at the dinner are asked to send their names and addresses to the House Governor, who will in due course give them further details of this notable occasion.

Society for General Microbiology

At the annual general meeting of the society the following were elected officers for the coming year: *President*: Professor J. W. McLeod, F.R.S.; *Hon. Treasurer*: Mr. H. J. Bunker; *Hon. Secretaries*: Dr. J. G. Davis (general) and Dr. W. E. van Heyningen (meetings). Full particulars of the work of the society may be obtained from Dr. Davis, 35, Villiers Road, Southall, Middlesex.

Register of Chiropodists

The 1949 Register of Chiropodists has now been published and medical practitioners can obtain copies free on application to the Registrar of the Board of Registration of Medical Auxiliaries, Tavistock House (North), Tavistock Square, London, W.C.

Honoured by Medical Library Association

Mrs. Eileen R. Cunningham, Librarian of Vanderbilt University School of Medicine, is the first recipient of the Medical Library Association's Marcia C. Noyes Award—a silver tray—in recognition of her outstanding achievements in medical librarianship. The award is named after one of the Association's charter members and its first woman president. A past president of the Medical Library Association (1947-8), Mrs. Cunningham is the author of *Classification for Medical Literature*, now in its third edition, as well as many papers on medical librarianship, medical bibliography, and medical history.

Medical Statistics

The General Register Office states that the classification of occupations to be used for the 1951 census will be similar to the one used for 1931. There are about 600 unit groups classified in 28 main groups. Each unit group has a three-figure code number. The Press Officer at the Ministry of Health can give further information on

'AVLON'

brand

PROCAINE HYDROCHLORIDE B.P.

Procaine Hydrochloride is one of the safest and most reliable of local anaesthetics. Its effect is rapid and powerful, but it has no central toxic action, it is non-cumulative and causes no liver damage.

Because of these advantages procaine is widely used, and is regarded by many authorities as the drug of choice for such purposes as regional, infiltration and spinal and dental anaesthesia. It has useful applications also in ophthalmology and rhinolaryngology.

For these and other uses as a local anaesthetic, 'Avlon' brand procaine hydrochloride is available in powder form and in sterile isotonic solutions of several strengths with or without adrenaline (1 in 50,000).

Powder: Bottles of 10, 50, and 100 grammes.

Sterile Solutions: 0.5%, 1%, 2%, 5% (with or without adrenaline) in bottles of 25 c.c. and 50 c.c., and ampoules of 2 c.c., 3 c.c. and 5 c.c.

IMPERIAL CHEMICAL (PHARMACEUTICALS) LTD.

A subsidiary company of Imperial Chemical Industries Ltd.

WILMSLOW, MANCHESTER

Why Ribena in Wounds and Fractures?

Because hypovitaminosis-C inhibits formation of reticulum and collagen, thus retarding healing and adversely affecting the condition of the resulting scar. Similarly it interferes with normal callus formation. Because, too, 'Ribena' is a particularly rich source of the natural vitamin-C complex 'Ribena' consists solely of the undiluted juice of fresh ripe blackcurrants and sugar; it provides a minimum of 20 mgm. of vitamin-C per fluid ounce.

Many surgeons employ 'Ribena' both pre- and post-operatively, particularly in operations on the gastro-intestinal tract and in orthopaedic procedures. Important indications also are cases on acute and chronic sepsis, such as contaminated wounds and infected sinuses. More detailed information will be gladly sent on request.

Rubena is the pure undiluted juice of fresh ripe blackcurrants with sugar, in the form of a delicious syrup. Being freed from all cellular structure of the fruit, it will not upset the most delicate stomach. It is particularly rich in natural vitamin C (not less than 20 mgm per fluid ounce) and associated factors

Ribena BLACKCURRANT SYRUP
(RIBES NIGRA)

H. W. CARTER & CO., Ltd (Dept. II A.)
The Royal Forest Factory, Coleford, Glos.

CONTROLLED SLEEP

The Bayer group of hypnotics, three members of which are described below, covers all degrees of insomnia.

'EVIPAN' A somnifacient of medium strength, rapidly absorbed and excreted. Sleep is induced in 10-20 minutes and the hypnotic effect lasts 3-6 hours.

'PHANODORM' A fairly powerful hypnotic for general use, inducing sleep within 30-60 minutes and maintaining it for 6-8 hours.

'EVIDORM' A rapid-acting hypnotic of medium strength. Sleep is induced in 10-20 minutes and lasts 6-8 hours.

The above products are supplied in packings of 10, 50, and 250 tablets.

A booklet entitled "The Bayer Range of Hypnotics" is available upon request.

"FOR THIS RELIEF MUCH THANKS..."

HAMLET, ACT 1, Scene 1.

Francisco's remark can find ample application in everyday usage and might well express the feelings of those who have obtained rapid relief from PAINFUL SPASMS of smooth-muscle organs.

Spascol
REGD.

Contains an important new synthetic anti-spasmodic, offering outstanding advantages over papaverine in the symptomatic treatment of SPASMS AND SPASTIC DYSMENORRHOEA.

1. RAPID AND PROLONGED THERAPEUTIC ACTION.
(1 tablet taken orally gives prompt relief, lasting from 3 to 6 hours).
2. NON-HABIT FORMING.
3. WELL TOLERATED.
4. EFFECT IS MAINTAINED BY A SMALL DOSE.

Packings of 10 tablets.

Samples and Literature on request

FORMULA: Each tablet contains 1—(3:4:5, triethoxyphenyl)—6, 7—dimethoxy-isouquinoline, 0.04 gm.; Hyoscine Hydrobrom, 0.0001 gm.; Ext. Belladonna, 0.001 gm.; Rhizome, Rhei, 0.005 gm.

classification to those concerned with medical statistics. By arrangement with the World Health Organization H.M. Stationery Office is obtaining copies of the *International Statistical Classification of Diseases, Injuries, and Causes of Death*. It will be published in 10 volumes and will replace the *Manual of the International List of Causes of Death* and the *Provisional Classification of Diseases and Injuries* issued by the Medical Research Council. The Ministry urges all hospitals to use this list, particularly in connexion with the national morbidity inquiry. One copy is being sent to regional hospital boards and boards of governors for each of their hospitals taking part in the inquiry. Information about the new list may be obtained from the General Register Office, Somerset House, Strand, London, W.C.2

ILLS

Mr Lionel Colledge, of Upper Wimpole Street, London, W.1, left 68,682. Dr Mul Ray Soni, of Withington, Manchester, left 27,327. Dr John Rea Henry, of Blaby, Leics, £13,100, and Dr George Williamson, of Murtle, Aberdeenshire, £48,741.

COMING EVENTS

Royal/Free Hospital School of Medicine

The Duchess of Gloucester will present the prizes and certificates awarded by the Royal Free Hospital School of Medicine in the Beveridge Hall, Senate House, University of London, Malet Street, W.C., on Wednesday, June 8, at 3 p.m.

Medical Superintendents' Society

The annual general meeting of the Medical Superintendents' Society will be held at B.M.A. House, Tavistock Square, London, W.C., on Thursday, June 9, at 10 a.m. On Friday, June 10, also at B.M.A. House, there will be a conference to discuss "The Problem of the Chronic Sick Patient." The annual dinner of the society will be held at Frascatti's Restaurant, 32, Oxford Street, London, W., on the evening of June 10.

British Association of Physical Medicine

A short course of lectures on the various aspects of physical medicine has been arranged on Tuesdays and Thursdays from June 9 to July 19, inclusive, at 5 p.m. They will be suitable for candidates preparing for Part II of the Diploma in Physical Medicine. Further details can be obtained from the honorary secretary, British Association of Physical Medicine, 45, Lincoln's Inn Fields, London, W.C.2.

Consultants' Meeting at Birmingham

There will be a general meeting of consultants in the Birmingham Region No. 12, at Nuffield House, Queen Elizabeth's Hospital, Birmingham, on Saturday, June 11 at 2.30 p.m., to discuss the proposed terms of service.

Faculty of Radiologists

The annual meeting of the Faculty of Radiologists will be held at the University of Sheffield on Friday and Saturday, June 17 and 18. The programme is as follows: June 17, 10 a.m., annual general meeting, 11 a.m., meeting of Diagnosis Section, discussion on "The Pulmonary Manifestations of Tuberculosis in Children," to be opened by Dr R. Margaret C. Macpherson. Dr John L. Emery, and Dr Thomas Lodge, meeting of Therapy Section, demonstration on "The Clinical Use of Radioactive Iodine" by Professor E. J. Wayne, Mr G. W. Blomfield, and Dr H. Miller, 2.30 p.m., meeting of Therapy Section, discussion on "The Problems of Organization Involved in the Use of Therapeutic Quantities of Artificial Radioactive Isotopes," to be opened by Dr A. S. McFarlane on "Distribution," Dr W. Arrol and Mr K. Fearnside on "Production," and Dr W. K. Sinclair and Dr J. J. Nickson on "Hospital Organization," 4.30 p.m., tea and tour of Sheffield National Centre for Radiotherapy, 7 p.m. for 7.30 p.m., dinner at Royal Victoria Hotel. June 18, 10 a.m., joint meeting of Diagnosis and Therapy Sections, discussion on "Metastatic Tumours of Bone," to be opened by Professor S. L. Baker, Dr F. Campbell Golding, Dr A. C. Crooke, and Mr G. W. Blomfield. An exhibition of radiographs, pathological demonstrations, and techniques in radiotherapy will be open throughout the meeting in the Department of Geography of the University. Full particulars of the meeting may be obtained from the secretary of the Faculty at 45, Lincoln's Inn Fields, London, W.C.2.

Films at London School of Hygiene and Tropical Medicine

Two films entitled "The African Schistosomiasis" and "Still Waters" intended for the instruction of the medical profession and for public education respectively, will be shown at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., on Thursday, June 30, at 3 p.m. The films have been prepared by the Health and Public Relations Departments of the Government of Southern Rhodesia.

Course in Bronchoscopy and Oesophagoscopy

A course in the theory and practice of bronchoscopy and oesophagoscopy will be given in Paris on July 3-14 by Professor Chevalier L. Jackson and Dr A. Soulas. Particulars may be obtained from Dr Soulas, 184, Avenue Victor-Hugo, Paris, 16^e.

Congress of Obstetrics and Gynaecology

The twelfth British Congress of Obstetrics and Gynaecology will be held at Friends House, Euston Road, London, N.W.1, on July 6-8. The programme is as follows: July 6, 10 a.m., Congress opened by the Minister of Health "Modern Caesarean Section," introduced by Mr McIntosh Marshall. 2 p.m., (1) Guest Paper—"Endometriosis," by Dr Joe V. Meigs (Boston, Mass.), (2) "The Methods of Assay and Clinical Significance of Pregnenediol in the Urine," introduced by Professor G. F. Marrian and Dr G. I. M. Swyer. 8.45 p.m., reception by the President and Council of the Royal College of Obstetricians and Gynaecologists at the Senate House, University of London, W.C.1. July 7, 9 a.m., meeting of the Central Committee of the Congress. 9.30 a.m., general business meeting of the Congress. 10 a.m., "Essential Hypertension in Pregnancy," introduced by Professor George W. Pickerniz and Professor F. J. Browne. 2 p.m., (1) "The Management of Pregnancy in Diabetes," introduced by Mr John Peel and Dr W. G. Oakley; (2) "Hernia of the Pouch of Douglas" introduced by Mr Charles Read. 8-10.30 p.m., reception by the President of the Congress and the London Committee in the Zoological Gardens, Regent's Park, N.W.1. July 8, 9.30 a.m., "Modern Concepts in Diagnosis, Prognosis, and Treatment of Carcinoma of the Uterus," (1) "The Diagnosis of Uterine Cancer by Cytology," by Dr J. Ernest Ayre (Montreal), (2) "Pre-cancerous Changes in the Cervix," by Professor Gilbert I. Strachan, (3) "Prognosis Based on Biopsies," by Dr A. Glucksmann, (4) "Partial and Complete Pelvic Exenteration for Uncontrolled Uterine Cancer: A Preliminary Report," by Dr Alexander Brunschwig (New York), (5) "Surgical Treatment of Carcinoma of the Cervix," by Dr Joe V. Meigs (Boston, Mass.). A discussion will follow, to be opened by Mr Victor Bonney (London), and continued by Professor Subodh Mitra (Calcutta) and others. 2 p.m., discussion on "Maternal Mortality," introduced by Sir William Gilliatt. 7.15 p.m. for 8 p.m., Congress banquet at Guildhall, City of London. Those intending to be present are asked to notify the honorary secretaries of the congress as soon as possible at 58, Queen Anne Street, London, W.1. The cost of the banquet at the Guildhall is 45s. Applications for ladies' tickets should reach the honorary secretaries by June 20. Associate membership entitling the holder to attend the meetings costs one guinea.

Medical Association of Eire

The annual meeting of the association will be held at University College, Cork, on July 7-9. The meeting will be addressed on July 7 by Dr Charles Hill, secretary of the British Medical Association.

SOCIETIES AND LECTURES

Monday

EDINBURGH UNIVERSITY—At Physiology Lecture Theatre, University New Buildings, Teviot Place, Edinburgh. June 6, 5 p.m., "The Renaissance and its Teaching" by Dr Douglas Guthrie.

Tuesday

EDINBURGH POSTGRADUATE BOARD FOR MEDICINE—At Anatomy Lecture Theatre, University New Buildings, June 7, 5 p.m., "Tuberculosis of Joints" by Professor Walter Mercer.

INSTITUTE OF NEUROLOGY, National Hospital, Queen Square, London, W.C.—June 7, 5 p.m., "Surgical Principles in Intracranial Surgery" by Sir Hugh Cairns.

INSTITUTE OF UROLOGY—At St Paul's Hospital, Endell Street, London W.C., June 7, (1) 11 a.m., "Pathological and Serological Diagnosis of Gonorrhoea" by Dr R. Thomson. (2) 5 p.m., "Disturbances of Micturition Due to Nervous Disease and Injury," by Mr Harland Rees.

LONDON UNIVERSITY COLLEGE—At Physiology Theatre, Gower Street, W.C., June 7, 5.15 p.m., "Muscular Contraction," by Professor A. V. Hill.

WRIGHT-FLEWING INSTITUTE OF MICROBIOLOGY, St Mary's Hospital Medical School, Paddington, W.—June 7, 5 p.m., "Electron Microscopy of Bacteria and Viruses" by Dr A. S. McFarlane.

Wednesday

INSTITUTE OF UROLOGY—At St Paul's Hospital, Endell Street, London, W.C., June 8, (1) 11 a.m., "Local Complications of Gonorrhoea in the Male" by Dr A. H. Harkness, (2) 5 p.m., "Infertility of the Male," by Mr A. R. C. Higham.

LONDON UNIVERSITY COLLEGE—At Physiology Theatre, Gower Street, W.C., June 8, 4.45 p.m., "Selective Toxicity with Special Reference to Chemotherapy" by Professor Adner Albert.

SOUTH-WEST LONDON MEDICAL SOCIETY—At Boleynbrook Hospital, Wandsworth Common, S.W., June 8, 8.15 p.m., "Modern Treatment of Heart Disease," Boleynbrook Lecture by Dr R. E. Rodgers.

Thursday

CLINICAL SOCIETY OF THE ROYAL FREE HOSPITAL, Gray's Inn Road, London, W.C.—June 9, 5.15 p.m., "Mammoplasty," by Dr. Ernesto F. Malbec (Director of Plastic Surgery at Hospital of Ramos Mejia, Buenos Aires). Visitors welcomed. (Change of date.)

EDINBURGH UNIVERSITY.—At Anatomy Theatre, University New Buildings, Teviot Place, Edinburgh, June 9, 5 p.m., "Mental Deficiency and Social Medicine," Honyman Gillespie Lecture by Dr. R. Bailey

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., June 9, (1) 11 a.m., "Ano-rectal Gonorrhoea," by Dr. A. H. Harkness; (2) 5 p.m., "Fistula of the Bladder (acquired)," by Mr. F. R. Kilpatrick.

LONDON: UNIVERSITY COLLEGE.—At Physiology Theatre, Gower Street, W.C., June 9, 4.45 p.m., "Some Aspects of Nitrogen Metabolism in the Mammal," by Dr. J. S. Bach.

LONDON UNIVERSITY.—At Institute of Neurology, National Hospital, Queen Square, London, W.C., June 9, 5 p.m., "Surgical Principles in Intracranial Surgery," by Sir Hugh Cairns.

RESEARCH DEFENCE SOCIETY.—At Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, London, W., June 9, 3.15 p.m., annual general meeting; "Physiological Research and the Vivisection Act," Stephen Paget Memorial Lecture by Professor C. Lovatt Evans, F.R.S.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, London, W.C.—June 9, 5 p.m., "The Mind of Mechanical Man," Lister Oration by Professor Geoffrey Jefferson, F.R.S.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—June 9, 4.30 p.m., "Psychiatry," lecture-demonstration by Dr. D. Curran

APPOINTMENTS

Dr. Hugh W. Jones has been appointed Director of the Department of Pathology and Clinical Laboratories of the Mason Clinic, Seattle, Washington, D.C., U.S.A.

Dr. Jones was formerly Chief of Pathology at the Walter Reed General Hospital, Army Medical Centre, Washington

FULHAM AND KENSINGTON HOSPITAL MANAGEMENT COMMITTEE.—The following appointments at Fulham Hospital are announced: *Senior Surgical Registrar*, N. N. Tereshchenko, F.R.C.S. *House-surgeon*, Margaret V. Bickerton, M.R.C.S., L.R.C.P.

MILLER, RICHARD GRAHAM, M.B., Ch.B., D.P.H., Divisional Medical Officer North-East Division, National Coal Board

PARKER, THOMAS, L.R.C.P. & S.Ed., L.R.F.P. & S.Glas., D.P.H., Administrative Medical Superintendent to Board of Management for Paisley and District Hospitals

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Buchanan.—On May 16 1949 at Birmingham, to Joan (née Macauley), wife of Ian Buchanan a daughter

Khidjan.—On May 22 1949 at Queen Victoria Nursing Institute, Wolverhampton to Doreen Elizabeth, wife of Wing Commander A. Khidjan, F.R.C.S. 1 son

Stone.—On May 19 1949, at 12, Avenue Road, London, N.W., to Lynn, wife of Dr. L. D. Stone of Uppminster, a sister for Gillian—Jacqueline Susan

MARRIAGES

Carlisle Hillary.—On May 14, 1949, at St. Martin-in-the-Fields, London, W.C., to Miss Marion Carlisle M.B. B.S. D.R.C.O.G., Ryton-on-Tyne, to June St. Hillary Hillary B.S., Auckland, New Zealand

Hoffman Large.—On May 28 1949, at the Chapel Royal, H.M. Tower of London to Arthur Hoffman M.B., M.R.C.P., to Catharine Elizabeth Large M.B. B.S.

DEATHS

Blarton.—On May 27 1949 at 4 Valley Road West Bridgford, Notts, John Frederick Barton M.B. B.S. aged 87 years

Polin.—On May 21 1949 at Upper Grange, Hinckley, Shropshire, Thomas John Polin M.B. B.S. L.R.C.P. & S.Ed. L.R.F.P. & S.Glas., late Wing Commander R.A.F.

Cummins.—On May 26 1949 at Oxford, Stevenson Lyle Cummins, C.B., C.M.G., F.R.C.S., Colonel late A.M.S., of the Priory, Thaxted, Essex

Lyons.—On May 21 1949 at Queen Alexandra's Military Hospital, Millbank, London, W.C., to Donald Lyons M.B. B.S. D.R.C.O.G., late Wing Commander R.A.F.

Greiner.—On May 27 1949 at Royal East Sussex Hospital, Hastings, Norman Greiner M.B. M.R.C.S. L.R.C.P. D.M.R.E. L.D.S. R.C.S., aged 62

Baker.—On May 22 1949 at Southend General Hospital, Jemima Brown Baker M.B. Ch.B. F.P. of 1, Tudor Way, Hockley, Essex

Spence.—On May 27 1949 suddenly at his home, 109, Lavington Road, Weymouth, Dorset, to Spence L.S.A. late of West Green, London, aged 70

Webb.—On May 27 1949 at 4 Claremont Villas, Cheltenham, John Curt Webb M.B. B.S. M.R.C.P. B.Sc. aged 50

Webb.—On May 14 1949 Henry Cadman Webb, C.B. M.R.C.S., L.R.C.P., late of 20, Festung Road, R.N. (retired), of 20, Festung Road, R.N. (retired)

Wetherby.—On May 27 1949 at 13 F. J. Road, Edinburgh, Charles Wetherby M.B. B.S. M.R.C.S. M.B. Ch.B. Collected, I.M.S. (retired)

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Abdominal Pregnancy

Q.—A recent question on abdominal pregnancy (March 5, p. 422) led me to read more about the condition. In none of the books consulted was a description of the diagnosis given. How is the diagnosis made, and what are the difficulties in diagnosis?

A.—The diagnosis can be difficult, and the condition is frequently overlooked if only because its rarity tends to put it out of mind. Many cases are recorded in which the real state of affairs was discovered only when an attempt was made to induce labour by rupturing the membranes. The patient may recall an attack of one-sided lower abdominal pain together with a little vaginal bleeding, regarded perhaps as threatened abortion, early in pregnancy—that is, at the time of extra-tubal rupture. Throughout pregnancy there may be attacks of abdominal pain with faintness and perhaps occasional decidual bleeding from the uterus. The patient sometimes complains of an undue amount of nausea, vomiting, flatulence, or colic, and the foetal movements cause pain; the pregnancy is "uncomfortable." The abdominal tumour tends to be asymmetrical and its borders are less well defined than those of an intra-uterine pregnancy. Contrary to the common account, foetal parts are not as a rule more easily palpated, but malpresentations are common. The gestation sac, unlike the uterus, does not contract, and another swelling—the uterus—may be felt alongside it.

On bimanual examination the key to diagnosis is identification of the uterus, moderately enlarged, separate from the main swelling. Ballottement of the presenting part cannot be elicited in the uterus. At the time of spurious labour the foetus dies; the cervix may open to some extent and the decidua be cast off. X-ray examination is often helpful. Instead of the uterine shadow around the foetus there may be translucent areas due to gas in the neighbouring bowel. The foetus is often in an abnormal position and shows unusual attitudes—"the flying foetus." Hysterosalpingography can confirm the diagnosis, but is rarely employed so long as there is any possibility that the pregnancy is intrauterine.

Urticarial Reaction to Penicillin

Q.—How common are urticarial reactions to penicillin, and are they likely to recur if a second course of penicillin is ever necessary? A patient received 200,000 international units of penicillin intramuscularly daily for eight days for a carbuncle in the neck. Ten days after the first injection a severe urticaria and angioneurotic oedema appeared. What is the position with respect to giving the patient penicillin again, either alone or with antihistamine drugs?

A.—Urticarial reactions to penicillin occur in a small proportion of cases. The rash usually clears up satisfactorily even if the penicillin is continued, and as a rule does not recur if a second course is given (Lyons, C., *J. Amer. med. Ass.*, 1943, 123, 1007). Intradermal tests with penicillin often have negative but occasionally positive results. An injection of 0.1 ml. of a solution of penicillin in a strength of 1,000 units per ml. of physiological saline may be made intradermally in the forearm, with 0.1 ml. of saline as a control in the other arm. The test areas should be examined after one hour and after six hours. If there is no marked weal or flare the test may be repeated in a strength of 10,000 units per ml. If the reactions to both tests are negative it may be assumed that urticaria is unlikely to recur should a further course of penicillin be given. If either is positive and a further course of penicillin is required, it is worth while giving antihistamine drugs from the beginning of treatment.

Absence of Abdominal Reflex

Q.—Is the loss of the abdominal reflex, either on one side or on both, evidence of an organic lesion?

A.—Bilateral absence of the abdominal reflexes does not necessarily indicate organic disorder, and is common in people beyond middle life, particularly if they are obese. The abdominal reflexes are very often lost after pregnancy, and in otherwise normal people they are occasionally absent or very difficult to obtain. Asymmetry of the reflexes is always evidence of organic disorder, but it must be borne in mind that this disorder may be anywhere in the structures subserving the reflexes, so that local injury—including abdominal operations—may lead to abolition of the reflex from one segment of the abdomen. After local causes have been excluded, asymmetrical loss of the abdominal reflexes may be taken as evidence of disorder in the peripheral or central nervous system, but usually such a diagnosis would not be made on the evidence of abdominal reflexes alone. Assessment of their significance can usually be helped, if there is associated asymmetry in the tendon reflexes or the plantar responses, or in the appreciation of sensory stimulation. Most neurologists make use of the abdominal reflexes in demonstrating a mild lesion of the pyramidal tracts based on observation of disturbed function or of a disorder of the deep reflexes, rather than the other way round.

Carriers of Salmonella

Q.—What is the best method of clearing up a *Salmonella* enteritidis infection in the intestine? A girl aged 11, who had diarrhoea for a fortnight and is now quite well apart from an occasional evening temperature of 99° F., is passing heavily infected stools. I understand she is likely to remain a carrier for many months unless this is treated. What treatment would you advise?

A.—Persistent carriers of the salmonella food-poisoning organisms are rare, but a fair proportion of cases excrete the organism for four to twelve weeks after the acute infection. These convalescent carriers become negative spontaneously, and it is doubtful if any local bowel therapy will accelerate the cure, since the focus of infection is probably the gall-bladder. However, a course of succinyl sulphathiazole or other poorly absorbed sulphonamide may be tried, while laxative or cholagogue medicaments may be prescribed to encourage a good flow of bile. If the carrier state persists for twelve weeks or longer the patient may become a permanent or chronic carrier. In such cases duodenal bile-stained contents should be aspirated to find out if the gall-bladder is in fact the seat of infection. If it is, it will usually be diseased, and cholecystectomy, which should carry very little operative risk in a healthy child of 11 years, may be advised with good prospects of cure.

The salmonella bacteria of the food-poisoning group are more resistant to penicillin and streptomycin than is the typhoid bacillus, and for this and other reasons chronic carriers of these organisms are unlikely to respond to treatment by antibiotics.

Nocturnal Frequency in a Diabetic

Q.—A patient aged 68 has had diabetes mellitus for twenty years, and despite 80 units of insulin daily has a fasting blood sugar level of over 200 mg. per 100 ml. He was for two months recently in bed with angina pectoris. He dreads the nights because he is unable to sleep, as he has to rise every two hours to urinate. What treatment do you advise to help him get a good night's rest?

A.—Further investigations are necessary before a diagnosis of the cause can be made. The question of enlarged prostate, either benign or malignant, and any other obstruction at the neck of the bladder, must first of all be excluded by a competent genito-urinary surgeon. If no abnormality is present, it is possible that the patient's blood sugar level during the night is very low indeed, as hypoglycaemia sometimes causes great frequency of micturition. The fact that the blood sugar level is over 200 mg. per 100 ml. fasting does not exclude the possibility that it may be very low between midnight and 8 a.m. If hypoglycaemia is the cause, an extra 10 to 15 g. of carbohydrate on going to bed will prevent the hypoglycaemia, and a further 15 g. of carbohydrate could be taken later on in the night if the patient is still troubled by frequency.

Pain after Coronary Thrombosis

Q.—Is short-wave diathermy of value in relieving the pain often present after an acute attack of coronary thrombosis? This pain may be in the substernal, submammary, cervical, or suprascapular region. Is there any contraindication to this form of treatment? For how long should it be continued? Can you suggest any drugs for the same purpose? Nitrites have been found not to give relief. The patient I have in mind is aged 53, with a blood pressure of 125/85 mm. Hg.

A.—Pain, apart from angina pectoris or a cardiac neurosis, is an uncommon sequel to an acute attack of coronary thrombosis. In the case mentioned the pain is not described as intermittent, nor is it affected by nitrites, so that angina of effort is unlikely. Its distribution is widespread for the pain of a cardiac neurosis, but if the pain during the thrombosis occurred over this area then this diagnosis is quite possible. Causes in the skeletal and muscular systems giving rise to referred pain in this area should be looked for, and, if none is present, reassurance and sedative drugs, such as phenobarbitone with theobromine and belladonna, should be tried. Short-wave diathermy has been used for the pain of angina of effort, with varying results. It is of little use, however, in cases following coronary thrombosis.

Dyspareunia

Q.—A married woman aged 26 complains of difficulty in coitus. She is keen to have a child, but some shock when she was 9 seems to have created a psychological reaction. I thought that graded glass vaginal dilators might help, but she wonders whether there is any danger of their breaking and has heard that they are painful in use. How should these dilators be employed, and should cocaine ointment be used with them, or would this be likely to have any adverse effect?

A.—Graduated glass or plastic vaginal dilators might well be helpful, but it is doubtful whether a patient of this type will be able to use them herself without first being shown how to do so by a doctor or nurse. The risk of their breaking is negligible. The smallest dilator should be passed first, and only when this can be done easily should the next size be tried. Any difficulty due to muscle spasm can be minimized if the patient adopts the dorsal position with the knees drawn up and concentrates on abducting the thighs. The muscle usually relaxes in response to gentle but firm continuous pressure on the dilator, and the dilator should be left in place for about fifteen minutes. Having reached the largest size, the dilator should be used once or twice daily, and left in for fifteen to thirty minutes each time, for two or three weeks before coitus is attempted again. It might be passed, too, immediately before the first few attempts at intercourse. A lubricant should be used with the dilators, but cocaine or other analgesic ointments are not very helpful, because the problem is not superficial tenderness but muscle spasm associated with nervous inhibition. If cocaine is used it is likely to be absorbed in small amounts, and might therefore produce a reaction in an individual sensitive to it.

Psychoneurosis and Neurosyphilis

Q.—Is the Ministry of Pensions entitled to a frank diagnosis of "neurosyphilis" in a patient to whom they have paid a pension for psychoneurosis for the past twenty years? If not, will the interests of the patient suffer if a non-committal answer is given?

A.—The first part of the question seems to be ambiguous. Presumably what is meant is that the patient, who has for twenty years suffered from psychoneurosis, has recently been found to have neurosyphilis. There does not seem any valid reason why this should be communicated to the Ministry of Pensions unless they specifically ask for it. The medical board examining the patient should be able to diagnose neurosyphilis; but if it asks for, say, the results of pathological examinations of the cerebrospinal fluid the information can hardly be withheld. It seems very unlikely that the patient has had neurosyphilis for twenty years unless he has had a considerable amount of treatment. There is no reason why a person suffering from psychoneurosis should not contract syphilis and subsequently develop neurosyphilis, but this latter could hardly account for mental symptoms lasting for twenty years, and the medical board would surely appreciate that.

Thyrotoxicosis and Pregnancy

Q.—A woman aged 35, who has had a swelling in the neck since the age of 21, has the classical signs of hyperthyroidism, but with a rise in the basal metabolic rate of only 22%. She is now five months pregnant. Is it advisable to treat such a case with thiouracil during pregnancy? Are the risks to the mother increased, and is there any risk that the foetus will be affected?

A.—It is usually wise to withhold thiouracil during pregnancy, as reports suggest that the drug may lead to goitre in the foetus. The patient in question, whose basal metabolism is elevated by only 22% in the fifth month of pregnancy, cannot have a severe grade of thyrotoxicosis, and it seems doubtful whether much additional risk will be incurred by allowing her to go to term.

Inheritance of Renal Calculi

Q.—A man aged 40 has suffered from oxalate calculi in the kidneys since the age of 16. He has had operations on both sides, but has been told that more stones may form. His father suffered from the same trouble, and he has avoided marriage for fear of transmitting the tendency to his offspring. I would be glad of information about the chances of inheritance of this disability.

A.—This is not an easy question to answer. The condition is relatively common, yet references to heredity in the literature are infrequent and vague. One would be tempted to dismiss inheritance as a factor of much importance and to conclude that the chances for any children of this patient are little worse than those for any random child, save that sometimes conditions in whose causation heredity appears to play little part do, very rarely, yield a history pointing to the operation of a gene in a particular family group. A fuller family history would probably help.

Painful Nodules on Heels

Q.—A woman aged 46 has for three years suffered from small painful subcutaneous nodules on the back and sides of both heels. Each nodule starts as a very tender spot, and a body the size of a pin's head can be felt, freely movable under the skin. For a month or two it increases in size and becomes less tender; at the end of three to four months it is the size of a grain of rice and comparatively painless. In the meantime another nodule has started which goes through the same slow process. The patient is otherwise in perfect health.

A.—Plantar warts would seem to be the most likely cause of the signs and symptoms described, and may be treated by soaking the affected areas in 3% formalin solution for ten minutes each night for six weeks. If this is not the diagnosis, biopsy and histological examination are suggested. Xanthomatosis or calcinosis cutis are possible but rare causes of such lesions.

Argyria

Q.—In a case of argyria in which the pigmentation is confined to the face, conjunctivae, and neck, is the condition likely to become worse on exposure to sunlight although the drug has been stopped? What lines of treatment do you advise?

A.—The discoloration in argyria tends first to affect exposed parts. It does occur on other sites and in internal organs. There is not much literature on the question raised, but experience would suggest that, once established, pigmentation is not likely to get progressively worse. There is no effective treatment.

Bundle-branch Block and Hypertension

Q.—A man aged 55 has bundle-branch block with pronounced cardiac hypertrophy and a blood pressure of 170/110 mm. Hg. The attacks of "palpitations" cause him great distress, and sometimes last a week. Can you suggest anything that might be helpful?

A.—The treatment in this case should be directed to the hypertension and consequent severe myocardial damage which are indicated by the cardiac hypertrophy. The bundle-branch block and the attacks of palpitation are a sequel to damage to the conducting tissue and myocardium respectively, probably due to interference with the coronary vascular supply. There are no symptoms of bundle-branch block, and no treatment for

it apart from the treatment of its cause. The attacks of palpitation may be due to the onset of complete heart-block, or more probably of paroxysmal tachycardia, fibrillation, or flutter. The exact condition should be determined by an electrocardiogram taken during an attack, the treatment being decided by its cause. This is essential.

Generally the patient should exert himself only within his cardiac reserve, and avoid undue fatigue, excitement, alcohol, and tobacco. He should have phenobarbitone gr. 1 (65 mg.) twice a day, "cardophylin" 0.2 g. three times a day, and be adequately controlled by digitalis. He should avoid causes known to induce attacks. For the attack, if due to paroxysmal tachycardia, experiments to discover a mechanism to cut short the attack should be tried, such as carotid-sinus pressure, not too vigorously undertaken in such a patient, abdominal pressure, cold drinks, and other well-known procedures. For this and for paroxysmal flutter or fibrillation, quinidine 6 gr. (0.4 g.) two-hourly for five doses should be given on two or three successive days. Potassium salts and phenobarbitone should be tried at the same time. If the attack is due to complete heart-block, adrenaline may be given. This is absolutely contra-indicated should the attacks be caused by tachycardia, fibrillation, or runs of extrasystoles. The prognosis appears to be very grave.

NOTES AND COMMENTS

Auricular Fibrillation in the Elderly.—Dr. MAX WINTERNITZ (USH nad Labem, Czechoslovakia) writes: Your questioner ("Any Questions?" April 9, p. 643) is told that "the only drug likely to prevent attacks (of auricular fibrillation in a man of 64 with no other signs of cardiac disease) is quinidine 3 to 5 gr. (0.2-0.32 g.) three times a day indefinitely." While this is a recognized scheme of treatment in such patients, there are other possible ways. My patients are asked to keep careful notes on the occurrence and duration of attacks for a control period during which sedatives only are given. When the spontaneous course of the disease has been established a test dose of quinidine is given to exclude idiosyncrasy, followed by 3 gr. thrice daily. This dose is increased to 6 gr. (0.4 g.) if the smaller dose has not reduced the frequency and duration of attacks. This treatment is continued if effective; if not it is discontinued. If attacks are infrequent and/or of long duration an attempt is made to shorten the individual attack by taking quinidine after the onset of an individual attack only—3 gr. every two hours until the attack ceases. Alternative attacks are treated at first, to decide whether quinidine has any shortening effect on attacks. If quinidine should prove ineffective a single dose of pulv. fol. digitalis gr. 25 (1.65 g.) is given, followed after two days by maintenance doses of 1.5 gr. (0.1 g.) per day. This may abolish the liability to further attacks in some cases; in others permanent fibrillation will be established. Most patients of the stated age will prefer a digitalis-controlled permanent fibrillation to the insecurity of sinus rhythm with frequent paroxysms of rapid arrhythmia. If neither quinidine nor digitalis prove helpful, and if the attacks are frequent and incapacitating, an attempt with thiouracil is justified, irrespective of the presence or absence of thyrotoxic signs. The dose should be on the higher side, and treatment must be protracted, in order to reduce the B.M.R. to subnormal levels, but the proneness to fibrillation will be significantly reduced in a high percentage of patients.

Vaccine Lymph.—Dr. L. G. JACOB (Bracknell, Berks) writes: An even simpler method of expelling vaccine lymph from capillary tubes than that described under "Preparations and Appliances" (May 7, p. 518) is by breaking off one extremity, passing the broken end of the tube through a flame, and then warming the contained air of the other end over the flame. With care there is no risk of inactivating the lymph by heat.

Dr. E. F. BLUMBERG, of King's Road, London, has also sent us a description of this method.

SUPPLEMENT TO THE BRITISH MEDICAL JOURNAL

LONDON SATURDAY JUNE 4 1949

THE SECRETARY REPORTS

PLUGGING AWAY

The General Medical Services Committee is in continuous negotiation with the Ministry, endeavouring to clarify the various points which have arisen during the first ten months working of the Service. While some of these points—taken by themselves—may not be regarded as of first importance they form in the aggregate part of the steady improvement in the terms and conditions of service.

For example, the Ministry has been urged to relieve the rural practitioner of what in some cases is an unusually heavy expense—namely, the charges incurred in telephone calls in making arrangements for a patient's admission to hospital. Evidence is being collected on the extent of this problem and particularly on the extent to which it has been aggravated by the National Health Service. It has been suggested to the Ministry either that a practitioner should be directly reimbursed for telephone calls made in connexion with the admission of his patients to hospital or that general authority should be given for the charges to be reversed.

The problems arising from the inflation of doctors' lists have also been the subject of discussion between representatives of the General Medical Services Committee and officials of the Ministry. This inflation arises from the inclusion in doctors' lists of names in duplicate which in turn arose from the fact that many insured persons under the old NHI scheme who were automatically transferred to the National Health Service list of their old panel doctor also completed a form ECI applying for inclusion in his list.

Other reasons for such inflation include

(1) Existence of a certain amount of inflation before the appointed day, partly from wartime difficulties and partly from the failure of some approved societies to notify "exits."

(2) The decision not to remove from doctors' lists the names of persons whose insurance was due to terminate on June 30 1948. The numbers were fairly substantial, consisting largely of people who had taken up work during the war or had continued to work when they might otherwise have retired, and who ceased to be employed between June 30, 1946, and Dec 31, 1946.

(3) The appearance of some persons' names on more than one doctor's list within the same executive council area. Some of these were insured persons before July 5, 1948.

(4) Removal of a person from one executive council area to another where registration is effected with a doctor in the new area without disclosure of the fact that the patient is on the list of a doctor in the other area.

Though strenuous efforts have already been made to improve the position there is still evidence of inflation in many areas. For example, in each of some twenty counties or county boroughs the number of patients on doctors' NHS lists is in the aggregate more than the population of the area. Discussions have taken place on possible means of checking this inflation, and the subject is still under review. In many areas the elimination of duplication will be a long process, owing to the need for inquiry where duplication is suspected but cannot be established from executive council records. The absence of the national identity number, the inclusion or omission of an initial, or change of address or marital status all give rise to difficulties in identification. Many cases will be resolved only by personal inquiry.

Another subject on which representations have been made to the Ministry is that of mileage in maternity cases. The committee's view is that a practitioner practising in an area where a mileage scheme normally operates should be entitled to a single payment for each maternity case booked, at the

rate of 3s a mile (outward journey) for the distance in excess of two miles between the practitioner's surgery and the patient's address. These mileage payments will be a first charge on the Central Mileage Fund.

At present a practitioner requiring an Aschheim Zondek test for pregnancy is required to refer his patient to the hospital, the decision whether or not the test can be undertaken resting with the hospital consultant. As a result of the Committee's representations the Ministry has agreed that general practitioners requiring an Aschheim Zondek test can obtain this by making direct application to the appropriate department of the hospital concerned, subject of course to the reservation that adequate facilities are available.

The Ministry has been asked to take action to relieve the position of those practitioners practising in the neighbourhood of a school who are frequently being asked to attend children for emergencies occurring at school without the patient's doctor having been given the opportunity of attending the case. The Ministry has undertaken to approach the Ministry of Education with a view to the issue of suitable instructions to school authorities to ensure that where possible the child's own doctor shall be called in for such emergencies.

One of the more unsatisfactory repercussions of the introduction of the National Health Service has been the delay in settling an appropriate fee for vaccination and diphtheria immunization undertaken by general practitioners. The Ministry's view has been that these services form part of the general practitioner's normal obligations to his patients under his terms of service and that any fee involved would be payable only in respect of the report to the local health authority and not on account of the actual service rendered. Discussions with the associations of local authorities could not proceed further on this basis. But as a result of further talks between the committee and the Ministry of Health it has been agreed that the submission of a report to a local health authority is *not* the only factor to be taken into account in assessing the fee. In the committee's view it would be appropriate for discussions to be reopened with the associations of local authorities, and it is hoped that a meeting for this purpose will be arranged shortly.

Hospital Medical Staffs

The Joint Committee of the Royal Colleges, the Royal Scottish Corporations and the Central Consultants and Specialists Committee, after reviewing the comments and recommendations of its constituent bodies, has conveyed to the Ministry of Health its observations on the proposed terms and conditions of service for hospital medical and dental staff. The Government's proposals in their final form are expected to be issued to hospital authorities and to the profession next week. As soon as the final document is received the Joint Committee will seek the view of its constituent bodies on the advice to be given to the profession on the question of acceptance of service.

The Central Consultants and Specialists Committee has decided to circulate the document to its regional committees together with a factual statement by its secretary.

The Joint Committee will meet on the morning of June 22 to consider the views of its constituent bodies on the question of acceptance of service.

Consultants and specialists have been asked not to enter into any form of permanent contract until the profession has determined its attitude.

A note on the Town and Country Planning Act will appear in these columns next week.

National Health Service

ADMISSION TO HOSPITAL

The following resolution was passed by the Local Medical Committee for the County of London on May 24 :

(a) That the Committee regrets that the letter dated March 15, 1949, from the Ministry of Health does not contain any constructive proposals for overcoming the difficulties which at present exist in connexion with providing hospital beds for acute cases, and draws attention to the fact that although four months have nearly elapsed since the matter was discussed with the Department's officers apparently nothing has been done; it therefore calls upon the Minister to take immediate and effective action.

(b) That, since the National Health Service Act gives no individual citizen the right to treatment in hospital, however acute the illness, and as hospital authorities are failing to provide such treatment and the service is thus lacking in an essential safeguard for the public, the Committee requests that, by administrative action and if necessary by amendment of the law, a duty should be placed upon hospital authorities which will ensure that cases in urgent need of admission to hospital are, in fact, admitted.

(c) That the Local Medical Committee makes the following suggestions regarding the admission of urgent cases to hospital :

(i) That an "admission medical officer" be appointed for each group of hospitals

(ii) That when the admission medical officer has received a request from a practitioner to admit a patient, and has satisfied himself that it is an urgent case, he shall take over from the practitioner the responsibility for finding a bed.

(iii) It shall then be the duty of the admission medical officer to endeavour to find a bed in one of the hospitals of the group.

(iv) That if no bed in the group be available the admission medical officer shall approach the admission medical officers in the adjoining groups

(v) That if the admission medical officer is still unable to secure a bed he is instructed to approach the Emergency Bed Service, who shall then become responsible for obtaining admission of the patient to any hospital

(d) That in order to minimize the difficulty occasioned by shortage or unequal distribution of nursing staffs, the Committee considers that as an emergency measure endeavours should be made to form a general pool of nurses, and, further, that authority should be given to the regional hospital boards to engage trained nurses at salaries in excess of the Rushcliffe Scale.

(e) That the Committee is of opinion that unless immediate action is taken there is a grave possibility of a complete breakdown of the service during next winter, which will prevent practitioners from carrying out their obligations under Clause 7(1) of the Terms of Service.

(f) That the foregoing resolutions be transmitted to the Ministry of Health, the General Medical Services Committee, the Public Relations Department of the B.M.A., the Executive Council, the four Metropolitan Regional Hospital Boards, and the Emergency Bed Service.

MATERNITY MEDICAL SERVICES EMERGENCIES

Where a doctor has been called in under the National Health Service, otherwise than by a local health authority midwife, to deal with a miscarriage in a woman who has not made previous arrangements for maternity medical services (or to deal with some other Period I obstetric emergency in similar circumstances), he may complete Form E.C.24 or 24A afterwards to enable him to claim payment of the Period I fee, provided that the emergency occurs after the end of the eighth week of pregnancy. Before that time cases requiring treatment would be dealt with under the normal arrangements for general medical services.

Emergency confinements qualify for Period II payments where the patient has not made previous arrangements for maternity medical services and the doctor is not called in by a local health authority midwife.

If the doctor called in is not on the obstetric list and not the patient's own Service general practitioner or his deputy, he would be expected to hand over responsibility to the patient's own doctor as soon as possible. The latter claims the fee and divides it with his colleague by mutual agreement.

TEMPORARY RESIDENTS

Payment for the medical treatment of temporary residents under the National Health Service, in respect of the first two quarters, was similar to that made under the National Health Insurance Act, each area receiving from the Central Pool the sum of 8s. for each temporary resident. It has since been decided, on the recommendation of the General Medical Services Committee, that the payment from the Central Pool shall be 15s. for each ordinary temporary resident and (provisionally) 2s. 6d. for each temporary resident in a convalescent home. The last figure will be reviewed in the light of experience and further information on the number of claims received.

The local distribution of the money received by each executive council under this heading will, as in the past, be entirely a matter for each area to determine by joint consultation between the executive council and the local medical committee.

Mileage for temporary residents will be a charge on the Mileage Fund and not on the Central Pool for treatment purposes.

HOSPITAL EYE SERVICE OPHTHALMIC OPTICIANS

The Ophthalmic Group Committee has considered certain questions relating to the staffing of hospital eye departments, and has expressed the view that ophthalmic opticians employed in the hospital service should be appointed on a full-time basis. It recognizes that in many areas this can be achieved only if the staffing arrangements are co-ordinated throughout the region in such a way as to provide scope for full-time posts, and for this reason the Group Committee considers that the appointment of ophthalmic opticians should be made at Regional level.

The committee is also of the opinion that, pending the establishment of the permanent eye service, ophthalmic surgeon should be required to give systematic instruction only to ophthalmic opticians employed at hospitals in a full-time capacity.

Regional hospital boards and boards of governors are being informed of the views of the Group Committee.

TRAINEE ASSISTANTS AND NATIONAL SERVICE

The Ministry of Health, after consultation with the General Medical Services Committee, has introduced a new condition into the conditions on which training grants are payable in respect of trainee assistants—namely, that in future the grant will not be payable in respect of trainees who are liable for military service.

HARROGATE MEETING RAIL TRAVEL ARRANGEMENTS

Members travelling by train to Harrogate are advised by the North-Eastern Regional Officer of British Railways to obtain seat reservations as soon as possible, as the normal traffic on these trains at this time of the year is heavy. These reservations should be made at the local railway station or through travel agents.

There are two pullman trains from London to Harrogate daily—viz., the Queen of Scots Pullman, which leaves King's Cross at 11.30 a.m., arriving at Harrogate at 4.2 p.m.; and the Yorkshire Pullman, leaving King's Cross at 5.30 p.m., arriving at Harrogate at 10.17 p.m.

The Queen of Scots Pullman also leaves Glasgow (Queen Street) daily at 10.15 a.m., Edinburgh (Waverley) at 11.24 a.m. and arrives at Harrogate at 3.48 p.m.

For the return journey a member of British Railway staff will be in attendance at Stand No. 12 in the Exhibition to be held in the Sun Pavilion throughout the period of the meeting, to make reservations on trains leaving Harrogate for various parts of the country.

GENERAL MEDICAL COUNCIL

ONE HUNDRED AND SEVENTY-FIFTH SESSION

The summer session of the General Medical Council opened at 44, Hallam Street, W., on Tuesday, May 24, 1949. Sir HERBERT LIGHTFOOT EASON presided.

PRESIDENT'S ADDRESS

The PRESIDENT delivered his address, of which an abstract follows :

Dr. J. W. Bone

My colleagues on the Council will, I have no doubt, have heard with the deepest regret of the death of Dr. Bone on April 14 after a long and serious illness.

During the twenty years of his membership he served continuously on the Public Health Committee, for whose work he was specially qualified as the holder of a Diploma in Public Health granted by the University of Edinburgh, of which he was a medical graduate, and on the Pharmacopoeia Committee, in whose work he took an unflinching interest as a general practitioner. When the Council appointed him a Treasurer in 1939 he became a member of the Finance Committee, and he was a skilful and vigilant chairman from 1944 until his death. He was a no less active and useful member of the Executive Committee from 1940, and he made well-informed and judicious contributions to the work of the Special Committee on the Curriculum from 1944 to 1947, and of the Legislation Committee first appointed in 1944. He had, further, been chairman since 1944 of the English Branch Council.

My own impression of him when he was first elected to the Council in 1928 as a direct representative for England was that he felt it was his mission to instil more life into, and effect some reforms in, what I think he considered rather an antiquated body. But as the years went on, and he got more familiar with the traditions and procedure of the Council, he mellowed considerably, and by the end of his long term of service he had become one of the stoutest defenders of the Council against uninformed criticism and misdirected schemes for its reformation.

His advice to the Council in their judicial work was invaluable in matters affecting general practice and the misdemeanours and errors that might be committed by members of his profession; and his opinion in this sphere rightly carried much weight, in that for many years he had been a most successful and honourable representative of general practice. We personally shall miss him very much owing to his sterling honesty, his kindness, and the enthusiasm with which he entered into every aspect of the Council's business. I feel sure that my very deep personal regrets at his death are shared by all my colleagues.

Other Personal References

The Council also have to deplore the death on April 10 of Mr. Edward Sheridan, a past president of the Royal College of Surgeons in Ireland and professor of dental surgery in University College, Dublin. Mr. Sheridan was an original member of the Dental Board established under the Dentists Act, 1921, and was the first member of the dental profession to be chairman of the Board when he succeeded Sir Francis Acland in 1939.

The death on Nov. 15 of Dr. Stuart McDonald, Emeritus Professor of Pathology in the University of Durham, will have reminded the senior members of the Council of a valuable service which he rendered to medical education on our behalf, though he was never one of our number, after his retirement from his Chair.

Members who knew Mr. Charles George Andrews as an officer of the English Conjoint Board or here will share the deep regret of his colleagues on the staff of the Council at his sudden death in the office on Jan. 14.

The Council will regret that we have lost the services and the presence of Mr. Robertson, who came here as a Crown nominee in 1946.

The Council have to congratulate Sir Wilson Jameson, who contributed so much to our counsels as a Crown nominee from

1942 to 1947, on being appointed a Knight Grand Cross of the Order of the British Empire. I think no man has had to serve the Minister of Health as Chief Medical Officer in a period of greater stress during his tenure of office than has Sir Wilson Jameson, and I think both those with whom he has worked and the public at large will realize what magnificent work he has done for the public health of England both before and, more especially, since he filled his present post. We ourselves deplored the day when he felt it incumbent on him to retire from the Council, and the honour that has been bestowed on him has given the greatest pleasure to all his former colleagues here.

We also have to congratulate our colleagues Sir Henry Cohen and Sir Sydney Smith on the honour of knighthood which has been conferred upon them. In their presence I will raise no blush on the cheeks of either of them by saying more than this, that in our opinion both of them have exceedingly well deserved this distinction.

The Medical Register

Members will have seen with interest that the *Medical Register*, which was a book of 335 pages when the first issue of it was published ninety years ago, has become so bulky that this year, for the first time, it is published in two volumes.

At the end of 1947 the *Register* contained the names of 77,929 practitioners, of whom 67,261 were registered on qualifications granted in the British Islands, 6,509, including 813 temporarily registered, in the Commonwealth List, and 4,159, including 3,748 temporarily registered, in the Foreign List.

The number whose names were added or restored to the *Register* in 1948 was 3,984, over 1,000 more than in 1947, and the highest on record. But at the end of 1948 the number of names in the *Register* was 76,292, or 1,637 less than at the end of 1947, and exactly the same as at the end of 1946.

This result follows from the substantial completion during 1948 of the heavy task of determining the position of practitioners eligible to apply for normal registration under the Medical Practitioners and Pharmacists Act, 1947, either by virtue of their temporary registration under Defence Regulation 32B or the Polish Resettlement Act, 1947, or as persons who served in a medical capacity in H.M. Forces overseas, or rendered analogous service to the Allied cause during World War II.

The primary effect of the Act was that the names of 1,396 practitioners were added to the Foreign List in the *Register*. Registrations in the Commonwealth List and in the local registers for England, Scotland, and Ireland, which made up the total addition of 3,984, did not vary materially in number from those in 1947.

So much for addition. Subtraction from the number of practitioners registered again turned mainly on the operation of the Act of 1947.

The names of 4,467 practitioners were removed from the *Register* on the determination of their temporary registration under the Act. Of these 3,119 did not apply for normal registration within the statutory time limit. We may safely assume that most of this great number are practitioners from the Commonwealth or from the United States of America who have returned to practise at home.

I am sure that the Council would wish me to take this opportunity of saying that the arid details of registration and removal from the *Register* do not obscure for us the immeasurable self-sacrifice and devotion of these medical men and women who joined the ranks of their colleagues here when the need was dire.

1,340 have become normally registered in the Commonwealth List or the Foreign List; and 8 have become normally registered on qualifications granted in the British Islands.

About 1,000 practitioners are known to have passed from the profession by death in 1948; and the total subtraction of 5,621 in the year was completed by two penal erasures and 144 non-penal erasures for failure to answer statutory inquiries about registered addresses.

Reciprocity with Canadian Provinces

One of the most important duties delegated by the Council to the Executive Committee under Section 9 of the Medical Act, 1858, has been since 1887 that of taking "the steps

time he was thinking of going into a practice made vacant by death—and he consulted the clerk to the local executive council, who suggested the Baguley estate. Consent was given to his going there, and after searching round for some time he obtained a surgery and started practice on Nov. 7.

He strongly denied that he had ever canvassed for patients. Asked why he called on Mrs. Thompson and Mrs. Winters, he said he was visiting a patient in the same block of flats and was told that those ladies wished to see him and register with him. He never said he was the doctor for the estate. The ladies welcomed him and said what an advantage it was to have a doctor near at hand. He did not discuss who their doctor was before transference, and he used no influence to get them to change.

Asked by the President whether he thought it wise to make such a call, he said that so many patients were asking to be registered at that time that he regarded it as the normal thing on a new estate. They were strangers to each other and to himself. The same sort of thing could never have happened at Stockport. At the time he thought there was no harm in responding to the request, but since these proceedings started his point of view had changed. With regard to the case of Mr. Parry, he was attending a patient next door to him, and on leaving he was approached by Mr. Parry, who, after asking after the patient, said how pleased he was to have a doctor so near, asked him to come into his house, and registered with him. Afterwards he treated him at his surgery for some time.

The President: Did you think it wise to go to his house in the first instance?

Dr. Wiseman: I was invited in.

The witness said that it was the same with other persons. He visited them because a request had been made for him to do so through a neighbour who was already a patient of his.

With regard to the notice displayed in the post office, he was wholly unaware that it was being shown until a complaint from Dr. Pearce was transmitted to him by the local committee. He did not put the notice up or ask the postmaster to do so, and immediately he heard about it he asked that it be taken down. It merely contained the words: "Messages may be taken here for Dr. Wiseman." No address or surgery time was appended.

In cross-examination, he denied that he had ever said he was the doctor for the estate, his words were "a doctor on the estate." In the course of further questions, Dr. Wiseman said he thought Dr. Pearce was the influence behind the statements of the various witnesses. Mr. Taylor was thereupon granted permission to recall Dr. Pearce, who denied that he had any personal motives or that he had called upon the several women named and asked them to make statements. He was not present when they made their statements, and it was not true that he had inspired a common formula in the statements. He agreed that he had asked people who had transferred from his list what had led them to do so.

At the conclusion of the evidence Mr. Richards addressed the Council on behalf of the respondent. Mr. Taylor desired to make a final speech on behalf of the complainants, but the President said that the custom in ordinary courts would be followed by the Council, whereby if no evidence other than that of the defendant himself were tendered on his behalf the Council for the complainants would not have the opportunity of making a second speech.

Judgment

After a lengthy consideration *in camera* the President stated that the Council had found certain facts proved—namely, that in or about November or December last Dr. Wiseman had canvassed patients of the practice of Dr. Pearce with a view to inducing them to become patients of his, in particular that he had canvassed Mr. George Parry with a view to inducing him and his family to become patients and had procured him to hand to him his medical card and the medical cards of his family as preparatory to the transfer of himself and his family to the respondent's list, and that he had canvassed in the same way Mrs. F. M. Thompson and Mrs. Sylvia Winters. In relation to the facts so proved the Council had judged him to have been guilty of infamous conduct within the meaning of Sect. 29 of the Medical Act, 1858, and in contravention of para. 6 of the Warnings Notice issued by the Council, and had instructed

the Registrar to erase from the *Register* the name of Michael Ansel Wiseman.

Mr. Richards: I take it that in view of that judgment the other charges are not proved?

The President: I have said the charges which are proved.

Convictions

The Council considered the case of Dr. Graham George Robertson, registered as of Mariners Lane, Tynemouth, who had been convicted at Tynemouth on Jan. 3 of driving a motor-car when under the influence of drink and had been fined £20 and disqualified from driving for 12 months. Mr. F. P. Winterbotham, solicitor to the Council, said that Dr. Robertson had been before the Council previously on similar charges, and in February, 1946, his name was erased from the *Register* but was restored two years later.

Dr. Robertson gave evidence as to this occurrence, which actually arose out of a New Year's Eve party. He submitted testimonials as to his excellent behaviour, and Mrs. Robertson gave evidence on his behalf.

The Council found the conviction proved, "but in spite of this temporary lapse the Council has decided neither to postpone judgment nor to direct the Registrar to erase your name."

The final case was that of Dr. Norman Fraser Stocks, registered as of Priestfield Road, Edinburgh, who appeared on two recent convictions of being in charge of a motor-car whilst under the influence of drink, one at Clay Cross in October, 1948, and the other at Berwick-on-Tweed in December, 1948.

Dr. Stocks, in reply to his counsel, Mr. A. W. Standing, said that he had had a nervous breakdown following severe war strain (he had been torpedoed whilst serving in the war). Counsel drew attention to his fine war record and to certain domestic difficulties.

The Council found the convictions proved but postponed judgment for 12 months.

ELECTIONS AND EDUCATIONAL BUSINESS

The following were elected by Council to be members of the Penal Cases Committee: Sir Henry Cohen, Dr. Dain, Dr. Gregg, Sir Cecil Wakeley, Dr. Waterfield, Dr. Campbell, Sir Sydney Smith, and Professor Picken.

Sir Henry Cohen, Dr. Brocklehurst, and Sir Andrew Davidson were appointed respectively chairmen of the Education, Examination, and Public Health Committees.

To fill the vacancy in the joint treasurership of the Council occasioned by the death of Dr. Bone, Sir Cecil Wakeley was appointed.

Dr. Brocklehurst, Sir Sydney Smith, and Mr. Stoney were appointed representatives of the three Branch Councils, for England, Scotland, and Ireland respectively, on the Dental Board.

Professor J. H. Biggart was nominated by the Council for appointment by the Minister of Home Affairs, Northern Ireland, as a member of the tribunal constituted under the Dangerous Drugs Regulations, 1938 (Northern Ireland).

Dr. Bigger, Dr. Hedley, Sir Sydney Smith, and Sir Cecil Wakeley were appointed to constitute the Finance Committee of the Council. Dr. Hedley reported that last year there was a substantial surplus in the Council's income, thanks to the registration of a large number of foreign practitioners under the Medical Practitioners and Pharmacists Act. This would not recur.

Sir ANDREW DAVIDSON presented a report from the Public Health Committee in which was set out for the information of the Council the statistics relating to D.P.H. courses and examinations since the new rules for the D.P.H. in 1946.

Sir LEONARD PARSONS raised the question of the large number of separate courses with the relatively small number of entrants.

Sir SYDNEY SMITH pointed out that with the larger rewards now obtainable in fields of practice other than public health it might be increasingly difficult to attract recruits into the public health service.

Professor PICKEN agreed that it was economically unsound to be running a large number of courses for a relatively small number of students attending any one course. But in view of the fact that it was not known at the moment how many people would be required in the public health field he thought it would be unwise to ask the universities to cut down their courses or

to attempt to combine the courses of different universities. He had himself tried to divert students to other centres, but had found it very difficult to persuade them. It would be as well to let the matter rest as it was at the moment.

The PRESIDENT said that the licensing bodies were independent. The Medical Act, 1886 (Sect. 21), said that they might combine, but the Council had no power to enforce combination. Such combination was certainly desirable, because a number of licensing bodies had only a small number of students and granted a small number of diplomas. The Council, however, could not interfere in the matter.

The report of the Examination Committee, submitted by Dr. Brocklehurst, contained the usual tables, and that of the Pharmacopoeia Committee, by Dr. Campbell, embodied a report of the Pharmacopoeia Commission, setting out its recent activities in the direction of nomenclature and of weights and measures.

The Council then considered *in camera* reports from its Executive and Legislation Committees, and the four-day session concluded.

Retirement of Mr. Hempson

At the conclusion of one of the cases at this session the President of the Council said that he understood this was the last occasion on which Mr. Oswald Hempson would appear before them. He first appeared before the Council as solicitor in 1918, and since then had appeared in many cases, either in his private capacity or as solicitor to the Medical Defence Union. The Council wished to express to him its high appreciation of his valuable services by his lucid presentation of the facts of a case and his skilful and intelligent advocacy. He carried with him into his retirement the best wishes of the Council. Mr. Hempson made a suitable acknowledgment and said what an honour he esteemed it to have appeared so frequently.

REPORT OF THE AUDITORS TO THE MEMBERS OF THE BRITISH MEDICAL ASSOCIATION

We have obtained all the information and explanations which to the best of our knowledge and belief were necessary for the purposes of our audit. In our opinion proper books of account have been kept by the Association so far as appears from our examination of those books and audited returns adequate for the purposes of our audit have been received in respect of the Scottish Committee. We have examined the above balance sheet and assessed income and expenditure account which are in agreement with the books of account and returns. In our opinion and to the best of our information and according to the explanations given us the accounts give the information required by the Companies Act, 1946, in the manner so required and, subject to Note 2 thereon, the balance sheet gives a true and fair view of the state of the affairs of the Association as at 31st December, 1948, and the income and expenditure account gives a true and fair view of the income and expenditure for the year ended on that date.

Questions Answered

Hospital Medical Staff Committees
define the functions of
statutorily

Q.—Please define the functions of the hospital medical staff committee as statutorily enacted? At my hospital the committee limits itself to minor matters of staff conditions, such as the canteen menu or the supply of table-tennis balls, which are not otherwise dealt with by the trade unions concerned. The medical superintendent informs me that the general policy of the hospital and the conditions regarding treatment of patients and staff interrelations are outside the committee's territory and are therefore not discussed. Is this the case?

A.—Hospital medical staff committees are not generally recognised. The Ministry of Health is not responsible for the B.M.A. The Ministry of Health is not responsible for the B.M.A.

A.—Hospital medical staff committees have no statutory recognition. The Minister of Health replied to a question in the B.M.A. Questionary (*Journal*, April 17, 1948, p. 742) as follows:

The Minister entirely agrees with the system of medical committees in hospitals. But he could not *compel* medical staffs to set them up (nor would the Association presumably wish him to try!). He has already included in his guidance to regional boards and hospital management committees a declaration of the importance which he attaches to the system and asked that every encouragement and facility should be given to it.

One of the points that were put forward in the Bill recommending Bill was that there should be a representative special committee of the hospital management committee.

One of the points that were put forward for inclusion in the amending Bill was that the Minister should recognize representative specialist staff committees (as he does local medical committees) at hospital management committee, regional hospital board, and board of governors levels, and that (as with the medical committees) he should prescribe the powers and duties of these committees from time to time as necessary. It was not included in the Bill. The profession would like to see these committees as internal committees of the Service, the executive bodies having a duty to see that they are set up, to give them access, and to encourage full co-operation. As initial functions it should be stated that such committees (a) shall have reasonable access at all times to their executive body, (b) shall, on being recognized, give prompt attention to requests from their executive body, and (c) shall be a normal and regular source from which executive bodies ask advice.

Dangerous Drugs Act: Restoration of Authority

Dangerous Drugs Act: Restoration of Authority
The Home Office announces that the authorities granted by the Dangerous Drugs Regulations under the Dangerous Drugs Act, 1920, have been restored to Dr. Robert Archibald Herschell Morison.

Locally Recruited C.M.S. Officers

SIR,—In the Memorandum on the Remuneration of Officers of the Colonial Medical Service (Annual Report of Council. Supplement, April 2, p. 205) you suggested that locally recruited medical officers should receive salaries less than the standard scale recommended, and that the proportion to be reduced is to be negotiated. May I ask who is to carry out the negotiation? Is it the B.M.A., which, as far as I am aware, has never shown any interest in "locally recruited medical officers," a number of whom are members of the Association and graduates of British universities and colleges?

I disagree with your suggestion of unequal pay, and advance the following in support, taking the African medical officer as an example:

It costs the African far more to obtain a medical officer than it does his British colleague. He, also,

It costs the African far more to obtain his qualifications in Britain than it does his British colleague; his living expenses are far greater. He, also, has to educate his children in Britain if there is to be any future for them. A perusal of the report of the Commission on Higher Education in West Africa, by the Rt. Hon. Walter Elliot will enlighten you on the state of education in the Colonies. Like his British colleague, the African medical officer undergoes frequent moves, and so also has to keep two homes. Social services in Britain have lightened considerably the responsibilities of the individual Briton to his family. No such services exist in the West African Colonies, so that the locally recruited officer has a greater burden to shoulder in this respect. Expatriation allowance based on the rate of the local officer's Harragin Commission appears to be the only concession made to another name the same thing. The African medical officer has to have a family in the Colonies, taking the African medical officer a

burden to shoulder in this respect. No such services exist in the Colonies, so that the locally recruited officer has Harragin Commission allowance based on the recommendations of the another name the *status quo* by which the British medical officer, having similar qualifications and experience, is paid 33½% more for doing the same job. This disparity in salaries has certainly not made for cordiality and co-operation between the two groups.

Finally, may I ask whether the interests of the locally recruited officers have ever been represented in your deliberations, and, if so, by whom?—I am, etc.,

London, W.C.1.

Finally, may I ask whether the interests of the locally recruited officers have ever been represented in your deliberations, and, if so, by whom?—I am, etc.,
London, W.C.1.

No Fee for Service
nts that M

OLADELE A. AJOSE.

No Fee for Service

SIR,—There are hints that Mr. Bevan, under the eagle eye of Sir Stafford Cripps, is unlikely to show much tolerance to the requests of general practitioners for an increase in the capitation fee for the first thousand patients on N.H.S. lists. There are

suggestions in the lay Press that doctors might well be permitted to augment their inadequate Treasury payments by charging patients a small sum for consultations.

In a leader in the *News Chronicle* of May 9, 1949, it is pointed out that some of the financial problems in the New Zealand Health Service have been solved by making patients pay a small charge for consultations, treatment, and the provision of aids to health. It is suggested that Mr Bevan should not shrink from similar charges if they can be shown to be necessary. To quote: "Until people understand how to use public services, a small contribution from their pockets might save the day financially, and it would be good for self-respect."

There may be many good arguments for charging patients a small fee, but one is doubtful of any enhancement of their self-respect by such a procedure. What of the doctor? Is he not going to squirm at having to stretch out his hand for his shilling or sixpence? A token of the doctor-patient relationship! In the confidential atmosphere of the consulting-room the patient is to confirm his trust in the family doctor by crossing his palm with silver. One can hear the less sensitive patient muttering, "Your tip"—the *pourboire* of the Paris taxi-driver. What of the much-advertised free Health Service?

Not all of our patients haunt the waiting-room. One does see pleasant patients who, with genuine ailments, come for the first time since the Service started. What would they think of us? They have made no demands on the Service until their first consultation, which is a right by Act of Parliament. A shilling a time from the man who requires a daily dressing or twice-daily penicillin injections from the woman with the inoperable carcinoma. A shilling a time to reduce the attendance of patients and augment the practitioners' incomes. Jangling of silver on a salver or in an empty dressings tin, or to be marked down to account. Why not a shilling-in-the-slot machine to open the waiting-room door? No, we simply could not prostitute ourselves in this manner.

If we are to maintain a good standard of medical practice and retain our self-respect we must not be unduly harassed by money matters. We must be paid adequately by the Treasury and we must not be distracted from our essential and exacting work by thoughts of inadequate finance or by the harsh rattle of coins. Let us insist on 100% action from the Whitley Council, the Association, and the democratically elected Minister of Health.—I am, etc.,

Kilmarnock, Ayrshire

IAN B.-K. MACGREGOR

Incidence of Sickness: Correction

SIR,—May I draw your attention to an error in the article "Incidence of Sickness" (*Supplement*, April 30, p. 254)?

Table I is said to present "Percentage of Persons Interviewed who had an Illness during the Month." These percentages have evidently been calculated from the data given in Table A of our *Quarterly Return* and refer not to persons ill during the stated month but during the three previous months.

The correct rates, which can be derived from our Table E, are as follows:

Percentage of Persons Interviewed Who Had an Illness or Injury during the Month

	1947		1948	
	16-64	65+	16-64	65+
July	58.2	79.2	61.5	79.3
Aug.	57.7	79.1	60.2	80.9
Sept.	63.2	80.0	63.3	81.1
July-Sept. average	59.7	79.4	61.7	80.5

Association Notices

ELECTION OF COUNCIL

The following are the results of the election of members of Council by those Groups where there were contests:

Group E (Bedfordshire, Cambridge and Huntingdon, Essex, Hertfordshire, Norfolk, Northamptonshire, and Suffolk)			
J. C. Pearce (Diss)	463	Elected	
A. Staveley Gough (Watford)	268		
No. of voting papers issued	2,637		
No. returned	731		
Group I (Metropolitan Counties)			
Lord Horder (W.I.)	1,696	Elected	
R. Hale-White (N.W.I.)	1,263	Elected	
F. Gray (W.C.I.)	866	Elected	
E. Steeler (W.I.)	847	Elected	
G. de Swiet (W.10)	699		
J. A. Gorsky (S.W.I.)	671		
R. Kelson Ford (S.W.10)	502		
J. F. Murphy (S.W.8)	432		
No. of voting papers issued	7,362		
No. returned	2,044		
Spooled papers	31		
Group K (Dorset and West Hants, South Western Wiltshire)			
J. A. Pridham (Weymouth)	484	Elected	
S. Noy Scott (Plympton)	350		
No. of voting papers issued	1,759		
No. returned	824		

In the following constituencies, for which no nomination papers were received, the Council appointed the practitioners named, under its powers under By-law 63 (2):

Group F (Berks, Bucks and Oxford, Birmingham and Staffordshire):

S. F. L. Dahne, Caversham

Group R (Northern Ireland): N. S. Dickson, Templepatrick.

CHARLES HILL,
Secretary

ANNUAL GENERAL MEETING

Notice is hereby given that the Annual General Meeting of the British Medical Association will be held at the Grand Hotel, Harrogate, on Monday, June 27, 1949, at 9 p.m. Business: (1) Minutes of the last meeting, held June 29, 1948; (2) Induction of President, 1949-50; (3) Balance Sheet and Income and Expenditure Account for the year ending Dec. 31, 1948. (4) Appointment of Auditors

CHARLES HILL,
Secretary

EXTRAORDINARY GENERAL MEETING

Notice is hereby given that an Extraordinary General Meeting of the British Medical Association will be held on Monday, June 27, 1949, at the Grand Hotel, Harrogate, immediately following the Annual General Meeting, when the following resolution will be proposed as a Special Resolution:

Resolution

That the Articles of Association be altered in the manner following:

(i) *Article No. 1*—By deleting the figures "1929" and by substituting therefor the figures "1948."

(ii) *Article No. 4 (1)*—By inserting before the word "voting" the words "receiving notices of General Meetings or of"

(iii) *Article No. 22*—By deleting this Article and by substituting therefor the following new Article to be numbered 22:

"22 The Association shall in each calendar year hold a General Meeting as its Annual General Meeting in addition to any other meetings in that year. Not more than fifteen months shall elapse between the date of one Annual General Meeting and that of the next. The Annual General Meeting shall be held at such time and place as may be fixed by the Council, and if no time is so fixed shall be held on Oct. 20 for if that day be a Sunday on Oct. 21), and if no place is so fixed shall be held at the registered office of the Association."

(iv) *Article No. 24*—By deleting this Article and by substituting therefor the following new Article to be numbered 24:

"24. The Council may whenever it thinks fit and (without prejudice to the provisions of the Companies Act, 1948) it shall

ANNUAL MEETING PROGRAMME: CORRECTION

In the Annual Meeting Programme (*Supplement*, April 23, p. 242), Combined Meeting of the Sections of Child Health and Preventive Medicine, the name of Dr. H. C. Cameron (London) was included in error.

upon a requisition made in writing as hereinafter provided by any one hundred or more Members convene an Extraordinary General Meeting."

(v) *Article No. 25.*—By deleting this Article and by substituting therefor the following new Article to be numbered 25:

"25. A requisition must state the objects of the meeting and must be signed by the requisitionists and deposited at the registered office of the Association, and may consist of several documents in like form each signed by one or more requisitionists."

(vi) *Article No. 26.*—By deleting this Article and by substituting therefor the following new Article to be numbered 26:

"26. If the Council does not within twenty-one days from the date of the deposit of a requisition proceed duly to convene an Extraordinary General Meeting, the requisitionists, or any one hundred of them, may themselves convene a meeting for the objects specified in the requisition, but any meeting so convened shall not be held after the expiration of three months from the said date. A meeting convened by the requisitionists shall be convened in the same manner, as nearly as possible, as that in which the General Meetings are to be convened by the Council."

(vii) *Article No. 27.*—By deleting this Article and by substituting therefor the following new Article to be numbered 27:

"27. In the case of an Annual General Meeting or of a meeting for the passing of a Special Resolution twenty-one clear days' notice at the least and in any other case fourteen clear days' notice at the least specifying the place, the day, and the hour of meeting, and in the case of special business the general nature of such business (and in the case of an Annual General Meeting specifying the meeting as such) shall be given in manner hereinafter mentioned to all the Members (other than those who under the provisions of the Regulations and By-laws are not entitled to receive the notice) and to the Auditors for the time being of the Association. The accidental omission to give notice to, or the non-receipt of notice by, any person entitled to receive notice shall not invalidate the proceedings at any General Meeting."

(viii) *Article No. 41.*—By deleting this Article and by substituting therefor the following new Articles to be numbered 41(a) and 41(b) respectively:

"41(a). The Council shall be composed of the President of the Association, the President-Elect, the immediate Past-President, the Chairman of the Representative Body, the Chairman and (during the year immediately following his period of office as Chairman of Council) the Past Chairman of Council, the Chairman of the General Medical Services Committee, the Chairman of the Central Consultants and Specialists Committee, and the Treasurer, *ex officio*, and of members of the Association elected by the bodies and in the manner prescribed in that behalf by the By-laws."

"41(b). No Member of Council shall vacate or be required to vacate his office as a Member of Council on or by reason of his attaining or having attained the age of 70 and any Member of Council retiring or liable to retire under the provisions of the Regulations or the By-laws and any person proposed to be elected or appointed a Member of Council shall be capable of being re-elected or reappointed or elected or appointed, as the case may be, as a Member of Council notwithstanding that at the time of such re-election or reappointment or election or appointment he has attained the age of 70, and no special notice need be given of any resolution for the re-election or reappointment or election or appointment or approving the election or appointment as a Member of Council of a person who shall have attained the age of 70, and it shall not be necessary to give to the Members notice of the age of any Member of Council or person proposed to be re-elected or reappointed or elected or appointed as such."

(ix) *Article No. 50.*—By deleting this Article and by substituting therefor the following new Articles to be numbered 50(a), 50(b), and 50(c) respectively:

"50(a). The Council shall once at least in every calendar year lay before the Association in General Meeting an Income and Expenditure Account for the period since the preceding account, made up to a date not earlier than the date of the meeting by more than nine months. The Council shall also cause to be made out in every calendar year and to be laid before the Association in General Meeting a Balance Sheet as at the date to which the Income and Expenditure Account is made up. Every such Balance Sheet shall be signed on behalf of the Council by two of the Members of Council and shall have attached to it a report by the Council with respect to the state of the Association's affairs and the amount, if any, which they propose to carry to reserves. It shall also have attached to it the Auditors' report and such other documents as shall be required by the Statutes to be annexed thereto."

"50(b). The Council shall also annually prepare an Estimate of the probable income and expenditure of the Association for the coming year and a Report of the proceedings of the Association for the past year and the Balance Sheet and Income and Expendi-

ture Account and the said Estimate and Reports of the Council shall be presented to the Annual Representative Meeting.

"50(c). A copy of each of the said documents shall be sent to the Secretary of every Branch and Division and published in the *Journal* not less than twenty-two days before the Annual General Meeting."

(x) *Article No. 51.*—By deleting from this Article the words "In addition to the above-mentioned Report."

CHARLES HILL,
Secretary.

June 4, 1949.

Branch and Division Meetings to be Held

FURNESS DIVISION.—At Ulverston Golf Club, Sunday, June 12, 2 p.m., annual golf meeting.

GREENWICH AND DEPTFORD DIVISION.—At Miller Hospital, Greenwich High Road, London, S.E., Wednesday, June 8, 8.30 p.m., annual general meeting.

METROPOLITAN COUNTIES BRANCH.—At B.M.A. House, Tavistock Square, London, W.C., Tuesday, June 7, 2.30 p.m., annual general meeting. Agenda: Induction of Dr. C. G. Martin as President of the Branch and President's Address, etc.

WESTMINSTER AND HOLBORN DIVISION.—At Holborn Town Hall, W.C., Thursday, June 9, 8 p.m., general meeting. Consideration of Annual and Supplementary Reports of Council, 1948-9; instruction of Representatives to A.R.M.

H.M. Forces Appointments

ARMY

Major-Generals W. Foot, C.B., M.C., K.H.P., and Sir Edward Phillips, K.B.E., C.B., D.S.O., M.C., late R.A.M.C., have retired on retired pay.

Brigadier (Temporary Major-General) K. A. M. Tomory, O.B.E., late R.A.M.C., to be Major-General.

Colonel R. D. Cameron, C.B.E., M.C., late R.A.M.C., to be Brigadier.

Colonel S. Arnott, C.B., C.B.E., D.S.O., late R.A.M.C., has retired on retired pay and has been granted the honorary rank of Major-General.

Colonels W. W. S. Sharpe, W. Russell, M.C., and G. T. Gimlette, late R.A.M.C., having attained the age for retirement, are retained on the Active List supernumerary to Establishment.

Colonel W. M. Cameron, C.B.E., late R.A.M.C., has retired on retired pay and has been granted the honorary rank of Brigadier.

Lieutenant-Colonels F. McL. Richardson, D.S.O., O.B.E., and J. W. Eames, from R.A.M.C., to be Colonels.

ROYAL ARMY MEDICAL CORPS

Major H. M. Rice has retired, receiving a gratuity.

Major S. W. Smith has retired on retired pay on account of disability. (Substituted for the notification in a *Supplement* to the *London Gazette* dated Dec. 31, 1948.)

TERRITORIAL ARMY RESERVE OF OFFICERS: ROYAL ARMY MEDICAL CORPS

Major (Acting Lieutenant-Colonel) A. Cowie, D.S.O., from Active List, to be Major.

Major E. H. Markby, from Active List, to be Major.

TRADE UNION MEMBERSHIP

The following is a list of local authorities which are understood to require employees to be members of a trade union or other organization:

Metropolitan Borough Councils.—Fulham, Hackney, Poplar.

Non-County Borough Councils.—Dartford, WallSEND.

Urban District Councils.—Denton, Droylsden, Houghton-le-Spring, Huyton-with-Roby, Redditch (restricted to new appointments), Tyldesley.

LUMBO-DORSAL SYMPATHECTOMY IN SEVERE HYPERTENSION

AN INTERIM SURVEY

BY

J. C. HARLAND, M.D., M.R.C.P.

Medical Chief Assistant and Registrar, Westminster Hospital

AND

F. d'ABREU, Ch.M., F.R.C.S.

Assistant Surgeon, Westminster Hospital

[WITH PHOTOGRAPHURE PLATE]

The treatment of hypertension by resection of the dorso-lumbar sympathetic nervous system has been practised for many years in the United States, where there is already an extensive literature on the subject. This literature has been reviewed elsewhere (Blodgett and Cutler, 1947; Bassett, 1948). It is only recently, however, that this treatment has attracted any great interest in this country. It might be helpful, therefore, to review a series of consecutive cases operated on at Westminster Hospital. The number—24 cases—is not large, and any conclusions can be only of a tentative nature. However, all these cases had been fully investigated before operation and have been carefully observed since, and an idea of the value of this form of treatment has begun to emerge.

Analysis of Material.—Of the 24 patients 15 were men, and of the nine women seven were married and two single. The youngest patient was a girl of 17, and the oldest a man of 60. The average age of the group was 42 years. There was no appreciable difference in age at operation between the men and the women. Six of the patients were over 50. The age incidence in decades was as follows. Under 20 years, 1 case; 20–29, 2 cases; 30–39, 4 cases; 40–49, 11 cases; 50–59, 5 cases; 60 years, 1 case.

Diagnosis

In five cases there seemed to be a cause for the hypertension: three patients had chronic nephritis, one patient had calculi in both kidneys, and the fifth, a married woman aged 47, had suffered from eclampsia 28 years previously. One patient with renal hypertension, a man aged 53 who had a clear history of acute nephritis at the age of 23, stated that his father and brother had both died from a "stroke." In this case the chronic nephritis had entered a malignant phase, and the familial tendency to high blood pressure had probably accentuated the disease. In the other 19 cases, in spite of careful interrogation and investigation, the origin of the hypertension was obscure, except that nine had a family history of hypertensive cardiovascular disease, suggesting that they might be cases of essential hypertension. However, when the records of these 19 patients were viewed as a whole an impression was gained that many were cases of chronic renal disease rather than essential hypertension.

Malignant Hypertension.—There were six cases of malignant hypertension in this series—four primary and two

secondary. The following criteria were used in making the diagnosis: (1) The presence of papilloedema with or without oedema of the surrounding retina—all six cases; (2) necrosis of the glomeruli or afferent arterioles on renal biopsy or at necropsy—five cases; (3) gross impairment of renal function—three cases; and (4) cerebrospinal fluid pressure greater than 300 mm. of water—two cases. Malignant hypertension may be a primary disease in a previously healthy person, or it may be secondarily superimposed on an existing renal disease. It is useful to make this distinction, as the primary cases have a prospect of greater and more permanent relief by operation. In one other case of renal hypertension the presence of a malignant phase was in doubt:

A married woman aged 50, who had suffered from severe occipital headaches for two years, had a blood pressure which varied between 180/120 and 300/170 mm. Hg, but was usually in the region of 240/150. Retinal examination revealed severe vascular sclerosis with occlusion of the right superior temporal artery. There was considerable retinal oedema, with many haemorrhages but only a few exudates and no papilloedema. The blood urea was 24 mg. per 100 ml. and the urea clearance 48% of normal. The cerebrospinal fluid pressure was 230 mm. of water. Pyelography revealed calculi embedded in both kidneys. Renal biopsy performed at operation showed necrotic changes in the afferent arterioles.

Symptoms

All patients had symptoms referable directly or indirectly to their raised blood pressure. Headache, often accompanied by severe lassitude, was the commonest. Only two patients did not complain of it, and in 13 it was the presenting symptom. Eleven patients had visual disturbances. Four had suffered from encephalopathic attacks before operation—an index of the severity of the hypertension in this series. Three patients had cardiac dyspnoea—paroxysmal in one and on exertion in the other two. Only three patients had prior knowledge (15, 14, and four years respectively) of their raised blood pressure. In all the other cases hypertension was a recent discovery.

Physical Findings

Blood Pressure.—In all patients the blood pressure was recorded on several occasions before operation. It was confirmed that the diastolic pressure gave a better indication of the severity of the hypertension. In only three patients

was the diastolic pressure constantly below 130 mm. Hg. The systolic pressure varied widely from day to day, sometimes by as much as 60-70 mm. Hg, but it was below 200 mm. Hg in only one patient. With rest in bed, most patients showed some fall in blood pressure, as shown by the accompanying table.

Blood Pressure (mm. Hg)	On Admission	With Bed Rest
Systolic:		
180-199	1 patient	7 patients
200-219	4 patients	4 "
220-239	6 "	7 "
240-259	8 "	6 "
260-279	4 "	—
280	1 patient	—
Diastolic:		
110-129	3 patients	10 patients
130-149	9 "	7 "
150-169	9 "	7 "
170-189	3 "	—

The effect of sedatives was investigated in five cases. "Sodium amytal," 3 gr. (0.2 g.), was given three times at hourly intervals, and the blood pressure was recorded at hourly intervals thereafter. The diastolic pressure fell below 90 mm. Hg in three of the five cases. The experience has not been large enough to estimate the usefulness of the test in selecting patients for operation.

Fundal Appearances.—The retinae were abnormal in all 24 patients—the six cases of malignant hypertension had papilloedema; 13 patients had haemorrhages and exudates, usually with retinal oedema, as well as arterial sclerosis; and five had arterial changes only; two of the latter had hypertensive heart disease, and one, a woman aged 52, was blind in one eye from an occlusion of the central retinal artery 16 years previously. Her blood pressure had been recorded as normal at the eye hospital she attended at that time.

Cardiac State.—This was assessed clinically, radiologically, and by electrocardiogram in all cases. Hypertensive heart disease was regarded as present when there was considerable cardiac enlargement and a grossly abnormal electrocardiogram. Four patients were considered to have this condition. Minor degrees of cardiac enlargement, usually observed radiologically, and minor electrocardiographic changes, such as diphasic or early inversion of T waves, were not considered indicative of this state. Congestive heart failure was not present in any of these four patients, but two had increasing breathlessness on exertion and one had frequent attacks of paroxysmal dyspnoea with blood-stained sputum and radiological pulmonary engorgement. The other patient, a woman aged 49, had no cardiac symptoms before operation, but one month afterwards developed congestive failure, from which she died four months later.

Renal Function.—The blood urea and the van Slyke urea-clearance tests were estimated in every case. The specific gravity of the urine was recorded daily, and often by depriving the patient of fluids for 12 hours in order to obtain the maximum urine concentration. Seven patients had a blood urea greater than 40 mg. per 100 ml., and five had a urea clearance of less than 70% of normal. Both tests were abnormal in three of the patients with malignant hypertension. The intravenous pyelogram was normal in 19 patients. One other had compensatory enlargement of the left kidney, and another had calculi in the lower calices of both kidneys. Excretion of the dye was poor in two of the patients with malignant hypertension. A retrograde pyelogram was normal in one patient with an equivocal intravenous test. A portion of renal cortex was removed at operation for histological examination on 12 occasions.

Although the appearance was abnormal in every case, and on the whole consistent with the clinical and pathological findings, not enough experience of this procedure has been acquired for an opinion to be given on its value.

Lumbar Puncture.—This was performed on 12 patients before operation. In nine the cerebrospinal fluid pressure was greater than 170 mm. of water, and greater than 300 mm. in two of the patients with malignant hypertension.

This series therefore consists of comparatively youthful patients suffering from severe hypertension. There is little that medical treatment alone can offer such patients, and the prognosis is always doubtful and often grave. As in addition symptoms were severe enough to interfere with their work and daily lives, it was felt that operation was justified.

Operation

The operative procedure in all cases was that of Smithwick and need not be elaborated, the coeliac ganglia, splanchnic nerves, and sympathetic chain being removed. The chain was excised in varying lengths, but never less than from the ninth dorsal to the first lumbar inclusive. The operation differs from that of other reported methods in that the coeliac ganglia were always excised. The amount of post-operative back pain could be diminished by resecting the twelfth (subcostal) nerve as fully as possible. All cases are now drained, owing to the difficulty in distinguishing between deep haemorrhage and post-operative hypotensive reaction, which undoubtedly caused the two deaths after operation. A blood transfusion was given only if there was appreciable haemorrhage from the drainage-tube.

Complications.—Two patients died as a direct result of operation, both from haemorrhage within 24 hours. A liability to haemorrhage due to increased capillary fragility is well known in severe hypertension. A pronounced fall in systolic pressure, with narrowing of the pulse pressure is a usual accompaniment of this operation, and as a result immediate post-operative haemorrhage is difficult to detect. There is considerable loss, too, of the usual autonomic response to haemorrhage, and profound shock quickly develops. Three patients had post-operative complications severe enough to delay convalescence—two had an empyema and the other developed a massive pleural effusion, which responded well to repeated aspiration.

In 11 cases the following minor complications occurred: pneumonia and atelectasis, 3; pneumothorax, 2; haematoma formation, 2; pleural effusion, 1; infection of wound 1; paroxysm of auricular fibrillation lasting for two hours 1; bulging of the abdominal wall due to section of the eleventh and twelfth intercostal nerves during operation, 1.

Mortality

In addition to the two post-operative deaths, three other patients have since died—in two cases two months and in one case five months after operation. All three were seen in the early stages of this investigation and were considered at the time to be gravely ill; they would not now be submitted to operation. Renal function was poor, and a necropsy the typical changes of malignant hypertension were found. Two died from uraemia and one from congestive heart failure, and operation appeared to have no effect on the progress of their disease.

Results of Operation

In one of the remaining 19 cases the operation remained incomplete because of an empyema which developed after the first stage. The other 18 have been observed for varying periods: over 18 months, 1 case; 12-18 months, 7 cases; 6-12 months, 9 cases; and 5 months, 1 case.

Effect on the Blood Pressure

This has been disappointing. After a temporary fall for a week or two the blood pressure starts to rise again and within three months has returned to the neighbourhood of the pre-operative figure. In only five of the 18 cases has the fall in blood pressure been appreciable, but even in these the final figure is well above normal.

No striking blood-pressure changes with alteration of posture have been observed. Only three patients have reported dizziness on standing up, and this was transitory. There was some fall in blood pressure in most cases immediately on standing up from the recumbent position, but this was no greater than could be accounted for by the ability of blood pressure in the hypertensive patient.

This failure to produce permanent lowering of blood pressure suggests that the effect of operation can at most be palliative.

Retinal Change

The improvement in the appearance of the fundus oculi has been as rapid and dramatic as that reported elsewhere (Bourne *et al.*, 1948). Retinal oedema, haemorrhages, and exudates have with one exception disappeared, and so far have not returned. This improvement is useful for purposes of record, and it may also represent a diminution in the rate of progress of the disease. It is felt, however, that there has been a tendency to lay undue stress on this fundal improvement, and a word of caution is necessary. The grading of retinal change suggested by Wagener and Keith (1939) is useful as a guide to severity, but its limitations should be appreciated.

In benign essential hypertension, the presence of retinal changes probably indicates a tendency to cerebral vascular accidents (Foster Moore, 1916-17), but not to heart failure or coronary artery disease. Also, many cases of benign hypertension have occasional exudates and haemorrhages which appear and reabsorb spontaneously over a period of years. Thrombosis of the retinal veins, too, may produce a startling fundus appearance without necessarily any worsening of outlook for the patient. Again, although exudates and haemorrhages cleared from the retinae of these patients, it was noteworthy that the vessels themselves showed little alteration even when only spasm was observed. Lastly, hypertensive retinopathy is commonly symptomless, and visual impairment slight unless papilloedema is present, or unless the patient is unlucky enough to have a patch of exudate or a haemorrhage over the macula or a thrombosis of one of the vessels, and consequently the improvement in fundal appearance is of less interest to the patient than to the observer. Therefore it is felt that this improvement should be regarded with caution.

Cardiovascular State

Perhaps the most urgently required information concerns the effect of this operation in hypertensive heart disease. Is there any prospect of improvement here as in the fundus oculi, or will the heart be as little affected as the blood pressure? Unfortunately this series is too small to provide an adequate answer, there being only four cases of hypertensive heart disease. Their case records are as follows.

Case 1.—A blacksmith aged 30 had suffered from attacks of paroxysmal breathlessness, occasionally associated with blood-stained sputum, for a month before his admission to Westminster Hospital in April, 1947. Apart from a similar isolated attack in August, 1946, his previous health had been good. His father had died from the effects of high blood pressure.

His physique was good, but the heart was enlarged, and radiography revealed pulmonary engorgement. Pulsus alternans, gallop rhythm, and rales at the lung bases were observed for

48 hours after admission, but there was no congestive failure. The blood pressure was 235/135 mm. Hg, falling to 180/120 mm. Hg with rest in bed. There was a sharp inversion of the T waves in lead I and left axis deviation in the electrocardiogram. The retinal arteries were thickened, and many exudates and a few haemorrhages were present. Renal function was normal.

Immediately after lumbo-dorsal sympathectomy in April-May, 1947, the blood pressure fell to 135/85 mm. Hg, but three weeks later it rose to 160/110. Two months later he was well, had gained 12 lb. (5.44 kg.) in weight, and not only had the heart decreased considerably in size and the lungs cleared radiologically, but the T waves in lead I were large and upright and the retinal exudates had disappeared.

Eighteen months after operation there had been no further breathless attacks, and he had been working continuously as a carpenter. He was slightly breathless on exertion, probably due mainly to obesity, as his weight had increased from 8 st. 12 lb. (56.25 kg.) at the time of operation to 11 st. 9 lb. (73.94 kg.). The blood pressure was 210/165 mm. Hg, and the retinae were normal apart from arterial changes. The lung fields were clear radiologically, but there was moderate enlargement of the left ventricle. The T waves were diphasic in lead I but negative in CR₁. (For chest films see special plate, Figs. 1, 2, and 3. ECGs of this case are shown in Figs. A, B, and C.)

FIG. A.—Case 1. Hypertensive heart disease. Electrocardiogram lead I before lumbo-dorsal sympathectomy. T wave sharply inverted.

FIG. B.—Case 1. Hypertensive heart disease. Electrocardiogram lead I two months after lumbo-dorsal sympathectomy. T wave now upright.

FIG. C.—Case 1. Hypertensive heart disease. Electrocardiogram lead I eighteen months after lumbo-dorsal sympathectomy. T wave now diphasic.

This patient appeared to derive considerable benefit from operation, although the heart is now enlarging again and the fall in blood pressure was only transitory.

Case 2.—A gatekeeper aged 42 had suffered from high blood pressure with persistent early morning headaches for five years, breathlessness on exertion and dizziness for four years, and for two months had felt very tired and unwell. The blood pressure was 230/150 mm. Hg, with persistent pulsus alternans, and the heart was considerably enlarged. The T waves in leads I, II, and CR₁ were inverted, with left axis deviation reversible by inspiration. Lumbo-dorsal sympathectomy was performed in May, 1948. Headache and dizziness ceased at once, and the

breathlessness slowly improved. Seven months after operation he was working, was feeling well, and became only slightly breathless on moderate exertion. His weight had increased from 9 st. 6 lb. to 11 st. 4 lb. (59.87 to 71.67 kg.). The heart size, however, was unaltered, and the blood pressure was 205/140 mm. Hg, although pulsus alternans had not been observed since two months after operation. In September the electrocardiogram showed that left axis deviation had disappeared and TCR₄ was upright, but T was still negative in the other leads.

Here objective improvement has not been striking, although subjectively the patient is much better, and for this reason it is felt the operation was worth while.

Case 3.—A married woman aged 47 had suffered from eclampsia 28 years previously. She had intermittent headaches for many years, and for five months had been breathless on exertion. There was no family history of high blood pressure. She was obese and there was moderate cardiac enlargement; the blood pressure was 230/150 mm. Hg. The electrocardiogram showed left bundle-branch block, and there were retinal arterial changes. Renal function was normal. A month after sympathectomy in December, 1947, the blood pressure was 145/90 mm. Hg, but a year later the figure was 240/140. Her heart, however, had not increased in size, and her breathlessness appeared to be mainly due to her obesity, as she had gained 9 lb. (4.08 kg.) in weight. Left bundle-branch block was still present.

Case 4.—A married woman aged 49 had suffered from high blood pressure for 19 months, associated with headaches, which ceased for three months with sedative treatment and then recurred. For a month she had blurring of vision in both eyes. The blood pressure was 220/160 mm. Hg, the heart was enlarged, and the lungs were engorged radiologically. T₁ was diphasic, the ST segments were depressed, and left axis deviation was present in the electrocardiogram. Sympathectomy was performed in May, 1948, but the blood pressure fell only to 180/140 mm. Hg. A month later she suddenly developed rapidly progressive congestive heart failure, from which she died in October, 1948. The post-mortem findings were those of congestive heart failure with malignant hypertension.

Malignant Hypertension

Four of the six patients with malignant hypertension are now dead. One died as a result of operation, two from uraemia two months later, and one from heart failure five months later. These last three patients stood the operation well, but the course of the disease was not delayed. The two survivors, both women, are now well and have shown considerable improvement. Their case histories are as follows.

Case 5.—A married woman aged 57 had for a month suffered from severe headaches, worse on stooping, with mistiness of vision. Both eyes showed gross papilloedema, with extensive haemorrhages and a few exudates around the disks (Plate, Fig. 4). The blood pressure was 270/140 mm. Hg, and the cerebrospinal fluid pressure was greater than 300 mm. of water. Radiological films of the skull, the electro-encephalogram, heart, and renal tract were all normal. Sympathectomy in March–April, 1948, only slightly lowered the blood pressure, but the papilloedema, retinal haemorrhages, and exudates rapidly disappeared (Plate, Fig. 5). The headaches also ceased, and seven months later she was well, although the blood pressure was still 260/140 mm. Hg.

Case 6.—A girl aged 17 complained of early morning headache, often associated with vomiting, for two years. Apart from transient mistiness of the left eye in August, 1947, her health had always been good. The blood pressure was 260/180 mm. Hg. There was moderate albuminuria, but no casts were seen, and the blood urea was 39 mg. per 100 ml. Mr. E. F. King reported on the retinae (Plate, Fig. 6): "There is retinal oedema particularly of the optic nerve heads and areas immediately adjacent. There is gross retinal exudate round the optic disks, and scattered exudates throughout the fundi, but only a few haemorrhages. Attenuation of the arteries and congestion of the veins is pronounced."

Renal biopsy performed at sympathectomy in March, 1948, showed the necrotic changes of malignant hypertension. Nine months later she felt well, had no headache, and her weight had increased from 8 st. 1 lb. (51.26 kg.) at the time of operation to 10 st. 12 lb. (68.95 kg.). The blood pressure was 180/120 mm. Hg. The vision in the left eye was poor (hand movements only), but good in the right eye. Mr. King reported: "Both fundi, left much more than right, show consecutive optic atrophy. There is extreme attenuation of the arteries, some in the left eye being completely occluded, and widespread retinal degeneration and some old retinal exudates. There are no recent haemorrhages and exudates" (Plate, Fig. 7).

In Case 6 the result has been particularly satisfactory, as the blood pressure has been significantly lowered, the malignant phase being replaced by a relatively benign hypertension. The fundal appearance, too, has considerably improved, although there is impaired vision due to consecutive optic atrophy.

General Health

Undoubtedly one of the most impressive features of this operation is the general improvement in health it causes. Headache, lassitude, and vertigo disappear, and the patients quickly acquire new energy. Most patients have returned to work, and often they must be deterred from working too hard. A significant gain in weight was noticed in 13 patients—sometimes of more than 2 st. (12.7 kg.)—and obesity has occasionally called for dietetic restriction. Only one patient, obese before operation, lost weight afterwards.

Discussion

Lumbo-dorsal sympathectomy has been performed in 24 cases of severe hypertension, 18 of which have been observed for varying periods up to 18 months. The high blood pressure has remained virtually unaltered, and for this reason the operation is expected to be only palliative. In spite of this, however, general health and vigour are improved, headache and lassitude have disappeared, and weight has been gained. Occasionally the heart may decrease in size and the electrocardiogram improve if hypertensive heart disease was not too severe before operation. Even if this does not occur, breathlessness on exertion may diminish and cardiac asthma disappear.

There is as yet little information to indicate which case of hypertensive heart disease will benefit most by operation or how long improvement will last, and the experience from the four cases recorded here is too small to give a clear guide. It is felt, however, that auricular fibrillation, congestive heart failure, past or present, and evidence of coronary artery disease are contraindications to operation. Patients with considerable cardiac enlargement, persistent pulsus alternans, gallop rhythm, or gross electrocardiographic changes are unlikely to improve, and should be submitted to operation only when other strong indicators are present. The following patient was refused operation on account of his cardiovascular state:

Case 7.—A man aged 48 had known of his high blood pressure and enlarged heart for five years. For two years before his admission to Westminster Hospital in February, 1947, he had suffered from intermittent headache, momentary double vision, and gradually increasing intermittent claudication. The blood pressure was 220/130 mm. Hg, with pulsus alternans. The heart was enlarged, and gallop rhythm was present. The retinal vessels showed arterial sclerosis, and no pulsation could be felt in the arteries of the feet. The blood urea was 36 mg. per 100 ml.

Rest in bed brought temporary improvement, but his headache recurred on discharge from hospital, and he became short of breath on slight exertion. In May, 1947, he developed a left hemiplegia. In May, 1948, the sudden onset of auricular fibrillation caused acute congestive failure, which responded well to treatment in another hospital. When seen in August, 1948,

here was considerable cardiac enlargement and auricular fibrillation. The liver margin was just palpable, with slight neck-vein engorgement but no oedema. The hemiplegia was unaltered. The blood pressure was 180/80 mm. Hg. His condition was considered to have advanced beyond the stage where sympathectomy was practicable.

It is considered that operation should be limited to relatively young people, as permanent arteriosclerotic changes are less likely to have occurred. Moreover, the disease generally progresses more rapidly in the young and intervention is more necessary. However, an upper age limit has not been adhered to rigidly, although any patient over the age of 50 requires special scrutiny. Each case should be viewed on its merits, and age should contraindicate operation only when permanent vascular disease is present, which with even merely a temporary lowering of blood pressure would make arterial thrombosis a serious hazard.

Malignant hypertension is not in itself a bar to operation. In fact, when the disease is primary it is especially indicated provided renal function has not seriously deteriorated. Two of the six patients in this series, both primary cases, are alive and have improved considerably. Operation seems to have "broken the vicious circle," and the malignant phase for the time being has abated. The prospect of relief of even a few cases of this grave condition is distinctly promising. In three of the fatal cases the patients were severely ill and had poor renal function, so their failure to respond caused little surprise. It must be emphasized that patients with poor renal function should not be submitted to operation. The blood urea should be less than 60 mg. per 100 ml. and the urea clearance greater than 50% of normal. It is doubtful if the operation is ever justified where the blood urea is greater than 80 mg. per 100 ml.

Operation may be performed in cases of hypertension secondary to some irremovable cause. There were three cases of chronic nephritis in this series, and some others may have had nephritis of the repens type, although there was no direct evidence of this. If the renal function is satisfactory progress of the disease may be slowed by operation.

Lumbo-dorsal sympathectomy then seems beneficial to young patients with severe hypertension who have severe symptoms, no substantial arteriosclerosis or gross heart disease, and good renal function. Such patients represent only a minority of all cases of hypertension, and operation will afford only partial relief. There is, however, considerable relief of symptoms, and the tempo of the disease appears to be slowed. Complete relief could hardly be expected seeing that the kidney remains uninfluenced, and for this reason it is felt that more extensive resections of the sympathetic nervous system, involving more than two operations with their additional hazards, are unjustified.

The advisability of operating on early cases of hypertension before the heart and other organs are affected may be considered. Should not hypertension in its larval stages be sought, as early cancer is sought, for surgical treatment? Such reasoning is fallacious, as the problems of cancer are dissimilar from those of persistent hypertension. Moreover, pathological change in response to raised blood pressure varies widely from case to case, although hypertension starting in youth usually has a graver prognosis than that beginning in later life. Nor can one tell whether a young patient with mild hypertension will go rapidly downhill or will lead a useful life for 10, 20, or more years. This being so, a surgical procedure involving two major operations in a patient who is virtually well is unjustifiable, particularly when the operation is not curative, and its late effects are

uncertain. For this reason operation was not advised in either of the two following cases.

Case 8.—A locomotive fireman, aged 27, for four years had attacks of momentary dizziness in which he did not fall. He had been under observation for two years, during which time his blood-pressure range was 200–170 mm. Hg systolic and 130–115 mm. Hg diastolic, except twice when figures of 140/95 and 130/80 mm. Hg had been obtained. His family history was healthy and his previous health good.

On admission to Westminster Hospital in May, 1948, he was rather apprehensive, and the blood pressure was 200/120 mm. Hg, but a daily record showed a consistently high figure. The cardiovascular system was otherwise normal. The urine was normal and he could concentrate to a specific gravity of 1030. The retinal arteries showed spasm in some segments but no exudates or haemorrhages. On sedation with sodium amylal the lowest blood pressure recorded was 130/95 mm. Hg.

Since then his blood pressure has remained consistently high, and he is considered to have essential hypertension, although he admits that "his nerves quicken every time he has his blood pressure taken." His dizzy attacks have ceased spontaneously, and his condition is not considered serious enough to warrant sympathectomy at present.

Case 9.—A married woman had in April, 1942, when aged 22, suffered for six months from high blood pressure with morning headache, nausea, and blurring of vision in the right eye. On examination the blood pressure varied between 260/200 and 160/130 mm. Hg, and the heart was enlarged. The retinae showed bilateral papilloedema, numerous haemorrhages and exudates, with a right macular fan and narrowing of the arteries. There was moderate albuminuria, with occasional hyaline casts. The blood urea was 36 mg. per 100 ml. and the urea clearance 49% of normal. Intravenous pyelography was normal. The cerebrospinal fluid was normal, but the pressure was 250 mm. of water.

Whilst in hospital at that time she had severe headaches, vomited frequently, and had an epileptiform convulsion, but later improved considerably, although on discharge the blood pressure was still 200/150 mm. Hg. In October, 1943, a pregnancy, her first, was terminated on account of her medical condition, but by June, 1945, her headaches had become less frequent and she returned to work. In February, 1946, she had an attack of slurring of speech and drowsiness lasting a week, and was readmitted to Westminster Hospital. With rest and sedatives her blood pressure fell from 210/130 to 160/100 mm. Hg. An electrocardiogram showed left axis deviation with inverted T waves in leads I and CR₁. Papilloedema, exudates, and haemorrhages were no longer present in the retinae, but her physical condition was otherwise the same.

On discharge from hospital she returned to light work, as her headaches had virtually ceased, and thereafter the blood pressure averaged 170/110 mm. Hg. On reassessment in April, 1948, the blood pressure fell to 140/95 mm. Hg with rest in bed, but the heart size was the same as in 1942. There were no exudates or haemorrhages in the fundi, and the cerebrospinal fluid pressure was 120 mm. of water. The blood urea was 39 mg. per 100 ml. and the urea clearance 40% of normal. She is still under observation, and is well.

This patient's condition shows a remarkable spontaneous improvement, over a period of six years, from a severe hypertensive state with encephalopathy to a relatively benign condition. If sympathectomy had been performed in 1942, as had been contemplated, her improvement would no doubt have been attributed to this. Her story indicates the difficulty of assessing such cases with a view to operation.

Another reason for not operating in the early stages is that a high blood pressure is often symptomless, and the patient seeks advice only when the heart or other organs are impaired. The disease may then be well advanced, even beyond the scope of sympathectomy, as in the following case.

Case 10.—A civil servant aged 46 had always been in good health until January, 1948, when he started to have recurrent

sore throats. In 1943 he had been accepted as a first-class life by an insurance company, the blood pressure then being 130/90 mm. Hg. In June, 1948, he was admitted to Westminster Hospital for tonsillectomy, and on pre-operative examination was found to have a blood pressure of 230/150 mm. Hg with pulsus alternans. There was no other cardiovascular abnormality, except that the fundi revealed exudates, haemorrhages, and vascular changes. The blood urea, however, was 120 mg. per 100 ml., and the urea clearance 26% of normal. Whilst in hospital he was free from symptoms and sympathectomy was not performed, on account of his poor renal function. He died from uraemia three months later.

Summary and Conclusions

Twenty-four cases of severe hypertension which have undergone lumbo-dorsal sympathectomy are presented. Their pre-operative state is described, and the results of operation are discussed. The following conclusions are reached: (1) the chances of permanently lowering the blood pressure are slight; (2) retinopathy, when present, may improve considerably; (3) there is not enough evidence to indicate clearly the effect in hypertensive heart disease—some patients may appear to improve temporarily, but this is unlikely with severe disease; (4) operation causes striking symptomatic relief, with notable gain in weight; and (5) in primary malignant hypertension the malignant phase may disappear.

In a properly selected case the relief is greater than that which can be obtained by medical treatment alone. Such cases are not numerous. The operation should be limited to severe and rapidly progressive cases with severe symptoms referable to their hypertensive state which comply with the following conditions: age less than 50 years, the renal function should be good, there should be no evidence of coronary or cerebral artery disease, and there should be no severe heart disease or heart failure.

Operation in early and mild cases is not advisable.

We are indebted to Sir Arnold Stott, Sir Adolphe Abrahams, Dr. W. E. Lloyd, Dr. S. P. Meadows, Dr. C. J. Gavey, Dr. F. D. Hart, and Dr. J. L. Lovibond, under whose care these patients were admitted, for permission to use their case records. We are particularly grateful to Sir Arnold Stott and Dr. C. J. Gavey for their continuous assistance and advice, and to Mr. E. F. King for his ophthalmic reports on these patients. We also wish to record our gratitude to Mr. C. E. Drew and Miss Joan Smith for help with the records and follow-up; to Dr. Peter Hansell for reproducing the chest films and electrocardiograms; and to Miss F. E. Stevens for clerical assistance.

Dr. F. M. Foote, executive director of the United States Society for the Prevention of Blindness, said in his address to the society's conference in New York: "Among the most serious eye problems that we must tackle is glaucoma. We are all deeply disturbed to know that at least 25,000 Americans are blind from glaucoma and approximately 150,000 more have lost the sight of one eye from this disease. We know that untold numbers of men and women over 35 years of age are working this morning in offices, in industry, in their own homes, unaware that they have early glaucoma—unaware that, unless they are fortunate enough to be among those discovered early, they will lose their eyesight so slowly, so gradually, that a large part of their useful vision will be gone before obvious symptoms bring them to the attention of a competent eye specialist. . . . The best estimates available on eye injuries in industry indicate that each year 100 workers are blinded and an additional 1,000 lose the sight of one eye. It should be possible, 40 years from now, to show that 90% of this unnecessary eye-loss has been prevented. If a man has defective eyesight, as in the case with 40% to 50% of industrial workers, he will find that safety glasses actually help him to do his job better if the hardened lenses are ground to include the correction he needs. Industry is in a position, therefore, not only to prevent accidental loss of sight, but also to help in preventing the loss of a skilled employee because of a visual handicap due to disease."

PAINFUL AMPUTATION STUMPS AND PHANTOM LIMBS*

TREATMENT BY REPEATED PERCUSSION TO THE STUMP NEUROMATA

BY

W. RITCHIE RUSSELL, M.D., F.R.C.P., F.R.C.P.Ed

(From the Department of Neurology, Radcliffe Infirmary, Oxford)

Current surgical practice concerned with amputation involves many measures which are designed to protect the stump neuromata from trauma or irritation. At the operation the nerves are often divided as short as possible, while most modern prostheses aim at avoiding pressure on nerves. In spite of these precautions pain in the amputation stump or phantom limb remains common (Sliossberg, 1948), and is often associated with spasmodic twitchings of the stump. The latter may become so violent that the term "epilepsy of the stump" is sometimes used; Weir Mitchell (1872) employed the term "chorea" to describe them.

The medical treatment of these cases has been disappointing, and the difficulties encountered in getting relief by surgical measures is evident from the current neurosurgical practice of treating some of these cases by excising areas of the brain.

The following case records, however, indicate that treatment at the periphery may, after all, prove successful by a very simple procedure. This possibility was considered for three chief reasons. First, in the normal limb nerve endings in the skin are rendered insensitive by occupation which involve repeated minor trauma or prolonged firm pressure on the skin. Secondly, conduction of a mixed nerve is easily interrupted by repeated pressure, without the production of any spontaneous pain. Thirdly, the regenerating nerve fibres in an amputation stump are likely to be no less vulnerable to minor trauma or pressure than are normal nerves and nerve endings. It seemed obvious therefore, that the effect of maintaining tender neuromata in a chronically concussed state merited investigation.

The first method tried was to deaden the neuromata with procaine and to percuss them for 10 to 15 minutes with a piece of wood.

Case 1

In 1937 a man aged 25 lost portions of four fingers of the left hand in a machine accident. He made a good recovery, and remained fit for work as a carpenter until February, 1942, when the palm of the left hand began to sweat excessively. One year later, while serving in the South African Army, he began to experience sharp stabbing pains in the phantom fingers and dorsum of the hand. On Feb. 28, 1944, the stellate ganglion was excised. The pain was relieved for two weeks, but then returned with great severity.

On examination in Cairo, four weeks after operation, Horner's syndrome was present on the left and the injured hand did not sweat. The ends of the amputation stumps were very tender, especially over some palpable neuromata. There was no sensory loss. On April 2 the digital nerves of the index-finger stump were injected with procaine, and then for about 15 minutes the end of the stump was hammered quite vigorously with a light piece of wood (a wooden test-tube container). This treatment was very successful, and the other tender stumps and scars were similarly treated. Thereafter it was found that if the patient two or three times daily tapped the tips of the amputation stump on a table for several minutes at a time, or if he applied prolonged pressure by handling tools firmly, he could keep all spontaneous pain and stump tenderness in abeyance.

*A preliminary report.

On April 26 he was using his hand freely without pain, and after designing and constructing a small wooden hammer, which he gave us for the treatment of similar conditions, he was discharged to duty on April 29.

Circumstances precluded the further study of such cases at that time. In recent months, however, six consecutive cases of intractable pain in amputation stumps and phantom limbs have been treated with such uniform success that this preliminary report seems desirable.

Case 2

A private aged 25 was injured by a circular saw in December, 1947. Both thumb and index finger of the right hand were severely damaged and partly amputated. After several plastic operations further amputations were carried out and tender neuromata were excised in January, 1949. The wounds healed, but the neuromata grew again quickly and caused great pain on attempts to use the hand.

On March 5, 1949, the neuromata were injected with procaine and percussed lightly for about 10 minutes. The patient was then given vigorous gripping exercises in order to cause pressure on the neuromata. Thereafter he continued to hammer the neuromata whenever the sensitivity returned. He found, however, that squeezing a piece of wood with his hand was most effective, and even on waking in the morning, when some sensitivity had returned, a few vigorous squeezes of a cricket-bail abolished the sensitivity.

Case 3

A soldier aged 24 was wounded in Italy in June, 1944. There were injuries to the right frontal region of the brain, the left eye, and the left shoulder. The left upper limb was amputated through the shoulder-joint.

When admitted to hospital in February, 1949, various aspects of his case were investigated, but only the state of the amputation stump need be considered here. There was considerable pain in the phantom arm, which consisted of the forearm, hand, and fingers in a position of flexion. There was a large stump neuroma, measuring nearly 2 in. (5 cm.) in diameter, which when pressed upon caused pain in either the radial or the ulnar half of the phantom hand.

Treatment by percussion to this neuroma first aggravated the phantom-limb pain, but after treatment for about five minutes the pain disappeared, and with it the phantom sensation for half the hand also vanished for at least an hour. A slight change in the position of the hammering deadened that half of the hand which was unaffected by the first treatment.

The neuroma in this case was difficult for the patient to reach himself, and it was found that the application of local pressure was more convenient. A golf-ball was bandaged to lie over the neuroma at the shoulder, and the patient, by leaning his weight on the ball for half an hour, succeeded in making the neuroma insensitive for some hours.

Case 4

A man now aged 47 was wounded in 1917 at the age of 16. He lost his right foot and had a below-knee amputation performed. The stump caused a lot of trouble, and several operations and re-amputations were carried out. Finally in 1920 a mid-thigh amputation was done. Severe pain in the stump and phantom foot continued, and six further operations were carried out between 1929 and 1942 to excise neuromata and spurs on the stump. In 1946 pain was again severe, and in August, 1946, the sciatic nerve was divided in the buttock and the distal part of the nerve removed. After this he was almost free of pain for a year; but again the pain recurred, and during the past three years it has been very troublesome and has become steadily more frequent and severe. The pain was severe during the day and kept him awake at night. He was taking both codeine and phenobarbitone tablets regularly. He could wear his artificial leg all day, but after walking for half a mile shooting pains and involuntary jerking of the stump forced him to stop. The pains were felt chiefly in the phantom foot, especially on its lateral aspect.

The patient was admitted to hospital on March 29, 1949, with a view to surgical division of the spino-thalamic tract. It was decided, however, first to try the effect of percussion treatment.

The amputation stump appeared healthy, but there were several tender spots which on pressure caused pain in the phantom.

Treatment was begun on April 2. Progress was good, and after three weeks he was discharged home. By this time pain in the phantom was infrequent, and could be quickly abolished by percussion. For periods of several hours the phantom disappeared entirely. The jumping of the stump also ceased. He had required no drugs, and had slept eight to nine hours every night for two weeks. A mechanical vibrator* was specially effective in his case, and for some hours after treatment there was neither pain nor awareness of the phantom.

When seen two weeks after returning home he reported that one or two short periods of hammering administered daily by his wife sufficed to keep the pain in abeyance.

Case 5

This patient, now aged 54, was wounded in 1918 in the right thigh. Chronic infection followed, and violent jerks of the wounded leg—it would jump right out of bed—led to high mid-thigh amputation in 1947. Pain in the phantom, however, became continuous from the day of the amputation. A tight pain in the lateral three toes of the phantom was particularly unpleasant. He could wear his prosthesis for only an hour at a time. The stump was healthy, but there were medial, lateral, and posterior tender spots which on pressure caused pain in the phantom.

Treatment was started on April 7, 1949, and proved to be very successful. Percussion with a mallet and applicator was specially effective, and the patient learnt to abolish all phantom pain by this method.

On discharge home on May 13 he was able to wear his prosthesis all day; he slept well without drugs, and the pain and jactitation of the stump were controlled by self-administered treatment for about 15 minutes daily. When seen a week after returning home the amount of hammering required to allay pain had become even less.

Case 6

This patient, now aged 59, was hit in the right knee by a shell fragment in 1918. Chronic infection followed, and a mid-thigh amputation was carried out in 1929. He remained free of all pain until November, 1948, when the stump began to jactitate in association with a "kicking" pain in the phantom leg. He found that a bandage applied to the stump so tightly that it ulcerated the skin was effective in arresting the jactitation of the stump.

Treatment was begun on April 22, 1949, and was very successful. It was soon possible for him to wear his prosthesis all day without either pain or jactitation. After treatment had been continued for a month he found that hammering for about 10 minutes twice daily was sufficient to keep the phantom-limb pain in abeyance.

Case 7

A man now aged 37 was wounded in the left foot on Oct. 24, 1942, and had a mid-leg amputation. He has been conscious of a phantom foot ever since, and the sensation of his great toe nail being twisted off was most unpleasant. There was also some jactitation of the stump at night.

The stump was healthy, but there were three very sensitive neuromata. Treatment was started on April 28, 1949. The sphygmometer cuff quickly rendered the neuromata insensitive for the first treatment, and the patient learnt to abolish both phantom and its pain by percussing the neuromata with a wooden mallet and applicator. If he treated the stump in the evening he could depend on having a comfortable night. He was discharged home on April 13, and a week later the amount of treatment necessary was even less.

When he was first treated percussion for 10 minutes abolished the phantom for about half an hour, but after two weeks one treatment of less duration abolished the phantom completely for four hours, while discomfort was avoided by one short period (five minutes) of treatment daily.

During percussion of the posterior neuroma this patient gave a vivid account of the temporary aggravation of the phantom sensations. These included reopening of the old wound of his

* The "Stanco" vibrator, as supplied by Stanley Cox, Ltd., 11, Gerrard Street, London, W.1.

foot, followed by a sensation of blood welling up between his toes. Percussion of a medially placed neuroma caused a temporary sensation of the nail being lifted off the phantom great toe. He generally felt he could move the phantom toes, but after treatment by percussion this subjective ability to move the phantom disappeared.

Present Plan of Treatment

The evolution of the best plan of treatment is still a matter for experiment, but the following method will be successful in most cases.

The use of a local analgesic before the first treatment has been discontinued as unnecessary, and instead a sphygmometer cuff is applied to the amputation stump and inflated to over 200 mm. Hg. Within two or three minutes the tender scars and neuromata become less sensitive, and gentle hammering with a wooden mallet or by means of a mechanical vibrator can be started and continued with increasing vigour for about 10 minutes. The blows of the mallet are usually transmitted to the neuroma through a wooden applicator (see below).

If the stump is too short for the sphygmometer cuff, hypalgesia of the neuromata can be obtained by prolonged pressure on them, and indeed the application of pressure is just as effective as hammering in abolishing the stump pain, as shown by the use of a golf-ball in Case 3.

During percussion or pressure on the neuromata a great variety of sensations are referred to the phantom foot or hand. These gradually become less, and the part of the phantom affected becomes numb and painless in 5 to 10 minutes if the strength of percussion is correct.

There are usually at least three neuromata in each stump, which should all be treated in the same way. Bruising of the stump should be avoided if possible, but if a bruise develops the next treatment can be applied to the nerve just above the neuroma.

After treatment the patient should wear his artificial limb for as long as he wishes—the more the stump is exercised the better. Jactitation usually ceases to be troublesome after the first or second treatment.

Treatment at first must be repeated at least twice daily, but before long one treatment a day is usually sufficient, and the patient soon learns to knock away his phantom pain whenever it becomes troublesome. A heavy mallet is required to treat neuromata buried under thigh muscles, but in other instances a light mallet may be adequate.

Repeated pressure is often useful, as in Case 2, while in a few instances the application of a sphygmometer cuff at a pressure of 200 mm. Hg for half an hour rendered the stump comfortable for many hours. This method, however, is probably not suitable for frequent use.

The patients soon learn the optimum period of percussion, and should each be provided with a suitable mallet and a wooden applicator with a smooth metal cap. For the applicator, half the handle of a hammer with a "dome-of-silence" on one end is very suitable if the rough edges of wood are filed smooth. The patients should continue treatment once or twice a day for several weeks; thereafter the duration and severity of treatment required should be ascertained by experiment in each case. Adequate information regarding the necessary duration of treatment is not yet available.

During percussion of the neuromata, but before the onset of general numbness in the stump, many sensations appear in the phantom that are of great physiological interest. Among these are, first, the reappearance of long-since-vanished parts of the phantom, and secondly the reappearance, as in Case 7, of pre-amputation sensations of the type described by Henderson and Smyth (1948).

Finally, it seems probable that some other painful conditions, such as tender scars, are just as easily relieved by this method of treatment.

Summary

The otherwise intractable pains and jactitations which sometimes occur in amputation stumps and phantom limbs may be abolished by repeated percussion of, or pressure on, the stump neuromata.

Repeated treatment by hammering or by a mechanical vibrator has proved to be highly successful in all of seven cases treated.

During treatment many interesting sensations appear in the phantom.

I am specially indebted to Dr. J. Spalding, who has assisted in this study, and to several members of the Ministry of Pensions medical administrative staff, who have encouraged this work and have referred patients for treatment.

CHEMICAL SYMPATHECTOMY

BY

H. A. HAXTON, M.D., Ch.M., B.Sc., F.R.C.S.

Consultant Surgeon, Crumpsall Hospital, Manchester

The interruption of sympathetic activity in the extremities is not now a new process; it dates back for over 20 years. Reviews of large numbers of cases (Telford, 1944; Haxton, 1947a) have established the value of this treatment for a greater variety of circulatory disorders than is generally appreciated, and much discomfort and suffering can be relieved by its application. In addition to its beneficial effects in arteriosclerosis, thrombo-angiitis obliterans, erythrocyanosis, poliomyelitis, Raynaud's disease, pernio, and erythromelalgia, sympathectomy has been found to effect a prolonged and apparently permanent cure of hyperhidrosis (Adson, Craig, and Brown, 1935; Telford, 1938; White, 1939; Haxton, 1948). But to achieve such benefits one or more open operations of a major character are required, and although the mortality rate is very small in expert hands (Telford, 1944) the treatment entails a good deal of discomfort and a convalescence of several weeks at least.

Patients who are in poor general condition are denied the benefits of sympathectomy, and although there is no fixed age limit comparatively few are treated by this operation after 60. Furthermore, a considerable number of sufferers from vascular disorders are not troubled seriously enough to justify the upset of open sympathectomy, and yet there is no doubt that their lot can be made much easier and their outlook improved by sympathetic interruption. It would seem, therefore, that there is a place for non-operative interruption of sympathetic activity if this can be achieved with little disturbance to the patient and with a lasting effect.

Paravertebral injections of 85% alcohol were introduced by Swetlow (1926) for anginal pain; but he aimed rather to anaesthetize the intercostal nerves than to block the sympathetic chain. The latter procedure was developed successfully by White (1935), who used alcohol to destroy the upper thoracic ganglia. Although a lasting interruption of sympathetic activity can be obtained, the injection of alcohol is followed in a considerable proportion of cases by a prolonged and painful neuritis. Ochsner (1943) states that the incidence of this complication is too high to make alcohol injection a justifiable substitute for open sympathectomy,

and the few cases which I have treated thus have confirmed this conclusion. De Takats and his co-workers (1946), too, have abandoned the paravertebral injection of alcohol because of the unpleasant complications.

Phenol in aqueous solution has been used to destroy periarterial and presacral sympathetic nerves (Doppler, 1926; Binet, 1933) mainly in gynaecological cases. Doppler decided to use 6% phenol after a trial of many substances, including acids, bases, alcohols, and ethers, and Binet reports experiments which demonstrated that painting with 5% phenol interrupts the conductivity in the cervical sympathetic chain of rabbits. There was, however, a considerable return of conduction within an hour. Mandl (1947) injected 0.2 ml. of 6% phenol into the cervical ganglion of cats and noted that the Horner syndrome persisted for 14 days. Degenerative changes were present in the ganglion for up to 45 days after the injection. He states that his solution causes no damage to other tissues—a conclusion reached also by Binet (1933). This evidence suggests that aqueous phenol should be a useful agent for paravertebral injection of the sympathetic chain in cases in which an interruption of activity longer than that provided by procaine is required. So far as can be determined, however, it has not been thus used by previous workers.

I have used such injections in the treatment of vascular disorders since March, 1947, and altogether some 220 cases have received one or more paravertebral injections of aqueous phenol. This experience has shown the treatment to be of undoubted value and worthy of addition to the surgeon's armamentarium. Only lower-limb cases will be considered here, as the application of the procedure to vascular disorders of the upper limb is still considered to be in the experimental stage and no conclusions may be drawn.

Method

The method has undergone several alterations in the light of investigations on the cadaver and by radiography after the injection of a diiodone-procaine mixture (Haxton, 1947b). Now two 12-cm. needles are inserted through skin weals 7 cm. from the midline and opposite the second and third lumbar vertebrae. These points are more lateral than is advised by American writers (Labat, 1922; White, 1935; Ochsner, 1943), but trial in the necropsy room shows that unless the needles are inserted with considerable obliquity they cannot be made to pass near the sympathetic chain. The needle must establish contact with the side of the vertebral body, and by manipulation it is persuaded to slide tangential to the bone for a further distance of 1 to 2 cm. The point may be felt to pierce the psoas fascia, and when it is in the correct plane a tentative injection of procaine should flow easily; in fact, a drop of fluid on the end of the needle is often sucked in. This indicates, rather surprisingly, that the intra-abdominal pressure is commonly sub-atmospheric.

A careful watch must at all times be kept for the welling of blood or cerebrospinal fluid from the needle. When the needle is correctly positioned a preliminary injection of 2 ml. of 4% procaine is made. As a rule the patient notices a feeling of warmth in the limb before this is detected by the observer, but the sole of the foot should begin to warm up within a few minutes of the injection unless there is severe organic arterial obstruction. Provided there are no symptoms of numbness or paralysis the injection is completed with aqueous phenol. It is important, however, that the whole technique of inserting the needles with accuracy should be mastered by careful practice in many cases before any injections of phenol are undertaken, because failure to place the needle point correctly may cause serious complications.

I believe that a more lasting effect is secured with 10% phenol in water than with a 6% solution, but at the former strength the solution and syringes must be kept warm or precipitation will occur. A total of 10 to 12 ml. is used as a rule, and this is well within the toxic dose, as Binet (1933) often injected 50 ml. of 6% phenol without untoward effects. No evidence of toxic reaction has appeared in this series. The patient remains in the lateral position for 15 minutes to prevent spread of the injection, and can then get up and go home if ambulant.

Results

When the needles have been accurately placed, warming of the corresponding foot has occurred within five minutes except in cases of severe arterial obliteration and when the feet have been very cold at the start. In more than 90% of cases a warm and dry foot has been obtained, and in 60% the effect has been a lasting one, the foot remaining warm and dry for months. In some cases in which the effect has not persisted the injection has been repeated and a good and lasting result obtained. The longest follow-up is now nearly two years, and the signs of sympathetic denervation remain. In two cases in which subsequent sympathectomy by open operation has been carried out there has been evidence neither of further improvement in the blood flow in the foot nor of greater symptomatic relief. Successful injection therefore results in a sympathetic interruption which is lasting and complete enough for practical purposes.

In the two cases in which sympathectomy was performed after phenol injection of the lumbar chain the interval in one was two days and in the other seven days. In both there was oedema of the tissues surrounding the chain—more pronounced in the earlier case—and some opacity of the sheath over the psoas muscle. The sympathetic chains looked swollen and their rami were easily broken. Histological examination of the chains revealed that the majority of the ganglion cells had lost their nuclei and were degenerating. A small piece taken from the anterior surface of the psoas major muscle showed some degeneration of the superficial fibres. A third patient, operated on five months after a phenol injection, had a fair amount of fibrosis in the vicinity of the sympathetic chain, and this made sympathectomy rather more difficult than usual. These observations show that phenol destroys the ganglion cells of the sympathetic chain and thereby produces the same effect as sympathectomy by open operation, and, further, that it causes little damage to surrounding structures.

Complications have been few, consisting for the most part of some irritation of the genito-femoral nerve. This develops in about 10% of cases and is manifest by hyperaesthesia in the groin, not often severe enough to cause great discomfort and lasting as a rule about three weeks. Only once has any more serious complication developed, and that was in an early case: an obese woman who developed signs of a low spinal analgesia lasting three hours and a weakness of the quadriceps on the injected side lasting three months. The needle was here incorrectly placed and the injection must have entered an intervertebral foramen. There should be no risk of such a complication if a 12-cm. needle is used and is inserted for its full length in obese patients.

A variety of conditions have been treated by "chemical sympathectomy," with the following results.

Hyperidrosis

One severe case affecting the feet was injected in October, 1947, with an immediate and dramatic cure which has remained complete. This demonstrates well the efficacy of phenol in producing a lasting interruption of sympathetic activity.

Erythrocyanosis and Perniosis

Six cases of cold blue legs with painful nodules of fat necrosis and, in some, chronic ulceration were treated with lasting benefit in all but one. Similar relief has been provided in two cases of severe chilblains.

Arteriosclerosis

Twenty-three patients have been treated for intermittent claudication, and the majority of these have stated that they benefited, some considerably. A few have had no benefit, but injection is always worth a trial, since there is a good chance that it will help the patient and the risk of harm is negligible.

The main field for sympathetic interruption is in the severer degrees of organic arterial occlusion due to arteriosclerosis with thrombosis in the arteries or, in younger men, occasionally to thrombo-angiitis obliterans. Severe ischaemia is indicated by pronounced colour changes between dependent and elevated positions of the leg and also by pain in the foot, which is worse in bed, and which, by interfering with sleep, rapidly exhausts the patient. This unhappy state can be greatly changed for the better by sympathectomy; much symptomatic relief is provided, and the risks of gangrene are reduced (Telford, 1944; Telford and Simmons, 1946). Chemical interruption by phenol injection has now been used in 65 such cases. It has given profound and lasting relief from rest pain in half of these and considerable relief in nearly all the remainder (Table I).

TABLE I.—Results of Chemical Sympathectomy with Phenol in 66 Cases of Arteriosclerosis of the Lower Limbs

	Relieved	Improved	Unchanged	Total
Pain	32	27	6	65
Claudication	2	21	13	36
Gangrene of toe	13	6	4	23
Ulceration	18	7	4	29

Pain due to inflammation in the neighbourhood of a gangrenous or infected part is not, however, relieved by this treatment or by sympathectomy. Phenol injections have greatly improved the precarious circulation in the foot, and in several cases with gangrene of one toe healing has been achieved with loss only of the affected digit. Patches of gangrene on the heel and chronic ulcers on the outside of the leg have likewise healed, with preservation of the limb. Patients have been very grateful for the relief afforded, and I have no doubt that the method merits a high place in the treatment of arteriosclerotic ischaemia in patients too old or otherwise unsuitable for open sympathectomy, and in those in whom the impairment of the blood flow is not advanced enough to justify the disturbance of an open operation.

Some of the arteriosclerotic cases have been complicated by diabetes mellitus and yet they have had good results. One woman with gangrene of both middle toes, with severe rest pain and intermittent claudication at 30 yards (27.4 metres), had one side injected, with resulting complete relief of pain in the ipsilateral foot and rapid healing of the gangrenous area. The patch on the other foot continued to spread and cause pain until that side was injected, after which rapid healing occurred. She was seen 18 months later and was symptom-free, with warm, dry, well-nourished feet and no claudication.

Venous Insufficiency

Fifty-eight cases of old white leg and similar deep-vein thrombosis have been treated by phenol injection with benefit to the patient in all but a few instances (Table II). After injection

TABLE II.—Results in 58 Cases of Chronic Venous Insufficiency of the Lower Limbs

	Relieved	Improved	Unchanged	Total
Ulcer	19	26	3	48
Swelling	6	16	28	50
Pain	24	19	3	46

tion patients have reported that there is less aching and tiredness in the leg, and the warm foot is often much appreciated. In some the swelling has been reduced, but this is by no means a constant sequel. The explanation of this improvement lies

partly in the removal of venous spasm, with a resulting fall in venous pressure, and partly in the improved nutrition of the capillary walls, with reduced transudation into the tissues.

When chronic ulceration has been present, often for many years, the injection has been followed by increased vascularity of the ulcer base, and healing has occurred in 40% of cases, although the patients remained ambulant and wore only tulle-gras and "viscopaste" dressings, well supported by crêpe bandages. In some cases supportive treatment alone had been tried for many weeks without effect. Any patient in whom a chronic ulcer of the leg due to venous insufficiency is associated with a cold and damp foot (evidence of sympathetic over-activity) now has a chemical sympathectomy as part of the treatment.

Conclusions

Sympathetic interruption by the injection of aqueous phenol has much to recommend it. Compared with open operation it is a relatively minor ordeal for the patient necessitating no rest in bed (most cases have been treated as out-patients). Sufferers from vascular disorders will much more readily submit to this than to the major operation of open sympathectomy, and the treatment can be employed in cases in which operation is considered unjustifiable because of the age and general condition of the patient or because the chances of improvement are insufficient—e.g., in claudication and chronic ulceration of the leg.

The injection results in destruction of the ganglion cells with a consequent interruption of sympathetic activity which can persist for two years at least. It is likely that some sympathetic activity will return in most cases, as indeed happens after open operation (Haxton, 1947b); but the method has the merit, denied to operation, that it can be easily and rapidly repeated if necessary. Complications are slight as a rule, and apparently much less troublesome than those following alcohol injections.

It must be strongly emphasized, however, that this method should be employed only by those who have had much experience with paravertebral injection of the sympathetic chain with local analgesics, since injection of phenol into the theca or a blood vessel would probably have serious consequences. In competent hands the method is a safe one, but the untried and untrained operator could easily cause disaster.

The sum total of suffering saved by this simple treatment has been very large, and patients have been extremely grateful for the relief provided, particularly since their pain and disablement have often been of long duration and many other treatments have been tried without benefit.

Summary

Six or ten per cent. phenol in aqueous solution has been used for paravertebral injection of the lumbar sympathetic chain in 200 cases. It destroys the ganglion cells and produces a lasting sympathetic interruption. Favourable results have been obtained in a variety of circulatory disorders, and complications have been few.

EOSINOPHILIC XANTHOMATOUS GRANULOMA WITH HONEYCOMB LUNGS

BY

THOMAS PARKINSON, M.D., M.R.C.P.

Medical Tutor, St. Bartholomew's Hospital, London; Clinical
Assistant, Brompton Hospital, London

[WITH PHOTOGRAVURE PLATE]

The precise nature of the Hand-Schüller-Christian syndrome is unknown. Originally it was thought that the various pathological changes were specific, and that they were due to abnormal intracellular lipid metabolism (Thannhauser, 1940). More recently it has been realized that the disease is probably a phase in a generalized disorder of the reticulo-endothelial system, and that it has certain features in common with eosinophilic granuloma of bone. The following case is reported as an example of the transition between these two diseases, and because, in addition to the recognized bony and pituitary manifestations, it shows pulmonary infiltration and polycystic, or honeycomb, lungs. So far as is known, no similar case has been reported from this country, and the occurrence of the disease in a subject of the patient's age is unique.

Case History

A boot-repairer aged 56 was admitted in September, 1948. In 1942 he had begun to notice breathlessness on exertion, and this symptom progressed slowly until his admission. In 1942 a radiograph of the chest showed diffuse pulmonary shadows, and he was treated for a short time in a sanatorium. A single specimen of sputum was alleged to contain tubercle bacilli, but this finding was not confirmed. In 1944 he had a fracture of the right femur, which occurred without local injury whilst he was sawing wood. Radiographs at this time showed a cyst of the femur at the site of fracture, but the fracture united in four months and no further investigations were undertaken. Nine months before admission there was a return of pain over the old fracture. In February, 1948, he suddenly began to suffer from excessive thirst and, soon after, from the passage of large quantities of urine. His thirst was such that he would often drink 20 pints (11.36 litres) of fluid daily. These symptoms were partially controlled by a proprietary pituitary snuff. Before the onset of these symptoms he had suffered from no serious illness. One of his sisters had died from pulmonary tuberculosis.

On examination he was seen to be a thin, normally proportioned man. There was no rash or abnormal pigmentation, and hair distribution was normal. Scattered rhonchi were heard over both lungs. The heart was normal; the blood pressure was 120/88. The liver and spleen were not palpable. A thickening of the right femur was palpable over the site of the old fracture. The nervous system was normal. There was no exophthalmos or any lymph-node enlargement.

Investigations.—A blood count showed Hb, 104%; red cells, 4,700,000; white cells, 10,000 (eosinophils 1%); sedimentation rate, 32 mm. in 1 hour (Westergren). Plasma proteins, total 7.8 g. per 100 ml. (albumin 5.6 g., globulin 2.2 g.). Serum cholesterol, 235 mg. per 100 ml. Serum calcium, 10.1 mg. per 100 ml. Serum alkaline phosphatase, 12 K.-A. units. The Wassermann reaction was negative. Vital capacity, 2,850 ml. (63% of normal). The hypertonic saline infusion test (Carter and Robbins, 1947) confirmed the presence of true diabetes insipidus.

Radiological examination showed a cystic area in the right femur immediately below the united fracture (Plate, Fig. 1). There was a generalized reticulation associated with milary mottling through both lung fields (Fig. 2). The reticulation formed small annular shadows about 0.5 cm. in diameter. Tomography confirmed the presence of small cystic areas in the lungs. There was no enlargement of the mediastinal glands. The skull showed irregular translucencies resembling exaggerated venous channels rather than lipid deposits. The

pituitary fossa was normal. The remainder of the skeleton was normal.

Biopsy of the right femoral cyst was made on material obtained from a small incision on the outer side of the thigh. Histologically the sections showed vascular granulation tissue with a cellular exudate. The cells were almost all eosinophilic granulocytes, but some lymphocytes and large mononuclear cells were present. No foam cells or lipid-containing macrophages were seen. The appearances were typical of eosinophilic granuloma of bone.

Treatment.—The diabetes insipidus was controlled by the injection of 10 units (0.5 ml.) of "pitressin tannate" once or twice daily. In November, 1948, a course of deep x-ray therapy was given to the right femur. There was complete relief of pain in the leg after the third day of treatment. In December, 1948, deep x-ray therapy was given to the pituitary fossa and then to the lungs. This produced no improvement in symptoms. The patient was last seen in March, 1949, when he stated that there had been no change in his breathlessness, and the dose of pitressin required to control the diabetes insipidus was the same. Radiographs of the chest and femur showed no change two and a half months after completion of radiotherapy.

Discussion

The term "eosinophilic granuloma of bone" was first used by Lichtenstein and Jaffe (1940) to denote a localized granulomatous condition of bone containing large numbers of eosinophilic granulocytes and giving rise to areas of cystic rarefaction. Otani and Ehrlich (1940) described similar cases earlier in the same year under the title of "solitary granuloma of bone." They found lipophages in biopsy material from one of their cases, but dismissed the possibility that the bony lesions were local manifestations of Hand-Schüller-Christian disease on the grounds that none of their seven cases showed evidence of generalized disease.

Previously, however, Fraser (1935) had reported four cases of the same condition as "skeletal lipid granulomatosis" and had described the pathological changes as taking place in three stages—namely, endothelial-cell proliferation, eosinophilic infiltration, and lipid storage. More recently it has become apparent that the local bony granulomata may be merely a part of a generalized disorder affecting the skeleton and viscera, and that other generalized reticuloses—namely, the Hand-Schüller-Christian disease and the acute reticulosis of infancy sometimes called the Letterer-Siwe disease (Abt and Denenholz, 1936)—may give rise to bony changes radiologically and histologically identical with those of eosinophilic granuloma. For these reasons it has been postulated that eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease are all variants of a common pathological disorder (Wallgren, 1940; Farber, 1941; Mallory, 1942; Jaffe and Lichtenstein, 1944). Thus Mallory (1942) found all grades of transition between the three disorders and concluded that in infancy the disease was manifest as the rapidly fatal Letterer-Siwe disease, later in childhood as the Hand-Schüller-Christian disease, and in older children or adults as eosinophilic granuloma.

Jaffe and Lichtenstein (1944) considered that the three disorders "represented a peculiar inflammatory reaction to some, as yet, unknown agent of infection," the distinctive histological features in a given case depending on the duration of the disease. In their opinion the presence of fibrosis and lipid-containing macrophages is merely indicative of chronicity. The increasing number of recorded cases which do not fall accurately into any one category, but which show features of all three diseases, has fully confirmed this view. It seems correct to regard eosinophilic granuloma as being a reticulosis with bony localization rather than a specific disease of bone.

As it is now accepted that these disorders are but phases of the same disease, it would be an advantage to have a single name to embrace the important features of all three. To avoid confusion in terminology Thannhauser (1947) suggested the name of "eosinophilic xanthomatous granuloma" as being descriptive of the main histological features. Until further knowledge is forthcoming on the aetiology of the disease this name should be adopted for the type of case described in this paper. The present case shows evidence of pulmonary, pituitary, and bony disease, and it is to be assumed that all three organs are affected by the same pathological process. The biopsy material from the bone showed granulation tissue and eosinophilic infiltration, and although lipophages were absent from this section it is probable, by analogy with other reported cases, that they may exist elsewhere.

That pulmonary infiltration occurs in eosinophilic xanthomatous granuloma has been recognized since Rowland (1928) described the case of a child aged 2 years who died from pulmonary fibrosis secondary to xanthomatosis. Since then many cases have been reported, and the recorded cases have been reviewed by Thannhauser (1940), Versiani *et al.* (1944), Weinstein *et al.* (1947), Ponseti (1948), Oswald and Parkinson (1949), and Schafer (1949). Oswald and Parkinson reported a case in which the granuloma gave rise to diffuse small cysts throughout both lungs, and they were able to find three similar cases in the literature. A similar case was reported by Schafer (1949). The case reported here shows the characteristic radiological changes of honeycomb lungs and is a further example of cystic pulmonary changes occurring in a more chronic phase of the disorder.

To clarify the protean manifestations of this disease it is suggested that eosinophilic xanthomatous granuloma should be regarded as a generalized disease of unknown aetiology, occurring in an acute or chronic form. In the acute variety, which occurs in infancy and early childhood, there is progressive infiltration of the skin, bones, lymph nodes, and viscera, leading to early death. The chronic variety, occurring in older children and adults, may present in a complete or an incomplete form. In the complete form there is pituitary, bony, and pulmonary disease, with possibly other visceral manifestations. In the incomplete forms, which are not uncommon, pulmonary, pituitary, and bony lesions occur either singly or in any combination. Thus, when the bony symptoms predominate the disease will be regarded as "eosinophilic granuloma of bone," and when the pituitary alone is affected it presents as diabetes insipidus.

It is the relation of the chronic form of this disease to pulmonary disorders that is particularly emphasized, for the possibility that lung fibrosis and cyst formation may be the sole manifestation of eosinophilic xanthomatous granuloma must be considered. It seems likely that such cases will arise, and confirmation of this concept is to be found in the association of pituitary disorders, transient or permanent, with honeycomb lungs (Oswald and Parkinson, 1949). Pathological evidence on this point is difficult to obtain, as in the chronic phase of the disease fibrosis obscures the histological picture. Further histological studies on this subject will be published elsewhere (Cunningham and Parkinson, in the press).

The response to irradiation therapy in eosinophilic xanthomatous granuloma is variable. In most instances the bony lesions respond symptomatically, and sometimes there is radiological improvement. The effect of irradiation on the pituitary and pulmonary disease is occasionally beneficial but usually without effect (Currens and Popp, 1943; Weinstein *et al.*, 1947; Ponseti, 1948). The present case had

complete relief of pain in the femur, but the diabetes insipidus and the respiratory symptoms were unaffected; there were no radiological changes following treatment.

A final point of interest in this case is the age of the patient. The oldest case previously reported was that of a man aged 50 (Versiani *et al.*, 1944).

Summary

A case of eosinophilic granuloma of bone in a man aged 56 is described. The patient also had diabetes insipidus and honeycomb lungs.

Irradiation therapy relieved the pain of the bony lesion but did not affect the pituitary or pulmonary disease.

The name "eosinophilic xanthomatous granuloma" should be used to include the three diseases commonly known as the Hand-Schüller-Christian disease, Letterer-Siwe disease, and eosinophilic granuloma of bone.

The occurrence of pulmonary manifestations in this disease is discussed.

I wish to thank Dr. Neville Oswald for permission to publish this case, and Mr. Norman K. Harrison, of the Department of Medical Photography, St. Bartholomew's Hospital, for the photographs.

ACUTE PNEUMONITIS IN A BERYLLIUM-WORKER

BY

G. RIDDELL ROYSTON, M.D., M.R.C.P., D.C.H.

[WITH PHOTOGRAPHIC PLATE]

The following case of acute bronchiolo-alveolitis is thought to be due to working in an atmosphere containing beryllium dust. It is believed to be the first acute case to be reported in this country.

Beryllium was discovered in 1797 by Vauquelin, who called it glucinum, owing to the sweet taste of its salts. It is a brittle steel-grey metal that is soluble in acids, and occurs chiefly as beryl, the double silicate of beryllium and aluminium ($\text{Be}_2\text{Al}_2(\text{SiO}_3)_6$). Phenacite (Be_2SiO_4) and chrysoberyl ($\text{Be}_2\text{Si}_2\text{O}_7$) also occur.

During the 1939-45 war beryllium was used in increasing quantities as an important component of certain alloys and for the production of phosphors for fluorescent lighting and gas mantles. The exact compositions of fluorescent mixtures for the manufacture of strip lighting are trade secrets, but they usually contain varying proportions of beryllium, zinc, manganese, and silica.

Case Record

A man aged 30 had been working in the laboratory of a radio factory for five weeks, when he developed shortness of breath on exertion and a slight unproductive cough. Dyspnoea became progressively worse, and three weeks later, on June 27, 1947, he attended hospital as an out-patient. There was no history of a haemoptysis or any symptoms of nasopharyngitis. His appetite was good, his bowels normal, and there had been no night sweats or unusual taste in the mouth. He felt perfectly fit and well except for his dyspnoea, though he thought he might have lost a little weight. His main disability was his dyspnoea on effort that interfered with his hurrying for a bus.

His occupational history revealed that from 1936 to 1939 he worked in a rolling mills, rolling zinc sheeting. There were no fumes. From 1939 to 1946 he was in the Army and served in North Africa and Italy, having what sounded like an attack of infectious hepatitis on returning to this country in 1946 and two attacks of malaria. He then worked for a year on a guillotine machine in a rolling mills, after which he started work in a laboratory of the radio factory. There he spent about two hours of each working day mixing the powders used for coating the insides of the tubes used for strip lighting. I was unable to determine the exact composition of this powder, as it was a trade secret, but beryllium and zinc were definite constituents. The actual mixing was done by hand by stirring the dry powders in a large bowl without a lid and without the aid of extractor fans or the wearing of masks. The atmosphere was heavily laden with dust during the mixing process. The dust settled in the laboratory, and during the day was no doubt often disturbed, becoming air-borne.

On examination on June 27 he looked well built and was without any cyanosis or finger-clubbing. He had an unproductive cough and became markedly dyspnoeic with the effort of undressing. Respiratory movements were good, and abnormal physical signs were confined to the lungs, where rhonchi and medium rales could be heard scattered throughout. These added sounds were not more pronounced at the bases. The heart appeared normal, and the blood pressure was 110/65.

As his dyspnoea was out of all proportion to the physical findings he was admitted on July 4 as a suspected case of tuberculosis. His subsequent progress was as follows. From July 4 until his discharge on Aug. 16 he remained afebrile with a normal pulse rate. By July 12 his symptoms had practically disappeared and added sounds could no longer be heard in the lungs. The erythrocyte sedimentation rate (Wintrobe), which on admission was 22 mm. in one hour, remained unchanged. Three specimens of fasting-stomach contents and one specimen of lung juice were all negative for tubercle bacilli both on direct examination and on culture. Seven specimens of sputum were similarly negative. A blood count on July 7 showed 104% haemoglobin (Haldane) and 8,300 white cells (4,814 polymorphonuclears, 2,656 lymphocytes, 332 monocytes, and 498 eosinophils). Cold agglutinins were present up to a dilution of 1 in 16 on July 10.

The x-ray appearances were of particular interest. The first picture (Plate, Fig. 1), taken on June 27, showed an indeterminate soft mottling, which in some areas was almost millet-seed. It was distributed all over the lungs, being especially marked in the lower zones and the axillary part of the right upper zone. It suggested an early miliary tuberculosis or possibly a sarcoid. The second picture (Fig. 2), taken a fortnight later, seemed to be typical of miliary tuberculosis. The appearance was unchanged on July 22, but a further picture on Aug. 7 (Fig. 3) showed considerable resolution. On Sept. 10 almost complete resolution had occurred without any evidence of fibrosis, and it became difficult to imagine that the condition was tuberculous. A final radiograph on March 5, 1948, was perfectly normal and showed no trace of the original changes.

Clinical Picture

Beryllium has on several occasions been blamed for causing illness. Two of the first accounts were by Zama-khovskaya (1934) and Martinskovsky and Syroechkovsky (1934), both of whom were quoted by Gelman (1936).

They considered toxicity could be attributed to beryllium fluorides, of which the oxyfluoride was particularly toxic. Gelman, discussing poisoning due to the vapours arising from the foundry method of extracting beryllium, considered that their special physical condition (great dispersion) explained their characteristic toxic effect, and that the tissue damage was due to the fluorine being separated from the oxyfluoride at the level of the bronchioles and the alveoli.

Two main types of respiratory disease have been described—the acute and the delayed. In the acute form Van Ordstrand *et al.* (1943) described three cases which they called chemical pneumonia, occurring in workers exposed to beryllium. The exact compounds were not stated, but the fluorides were specifically excluded. They considered the aetiology unknown, having seen a similar case in a worker in a rayon factory where there had been no exposure to beryllium. These cases all presented insidiously, with increasing dyspnoea on exertion, a dry cough, low-grade fever with shallow respirations, some cyanosis, and fine rales throughout the lower halves of both lungs.

The onset of the symptoms preceded the x-ray changes by three weeks or more. The x-ray changes started with diffuse haziness of both lungs, progressing to soft irregular areas of infiltration accompanied by increase in the peribronchial markings. This was followed by absorption of the diffuse infiltration and the appearance of a small nodular infiltration which cleared completely within one to two months. Six additional patients from the same beryllium plant were all found to have identical radiological changes.

Van Ordstrand *et al.* (1945) had 128 cases with respiratory manifestations over a period of four years; 38 of these, including five fatalities, were described as chemical pneumonitis. The onset of symptoms was insidious, with cough and occasional blood-stained sputum, followed by dyspnoea, an abnormal taste in the mouth, anorexia, and some loss of weight and increasing fatigue. Of the signs, cyanosis was usual, with rapid pulse, reduced vital capacity, and fine rales scattered throughout the lungs. X-ray changes were not usually present until two to three weeks after the onset of the disease and were as already described (Van Ordstrand *et al.*, 1943). They cleared in from one to four months, and it is emphasized that as a rule this was before complete subsidence of the symptoms or disappearance of the physical signs, though in one case they persisted for a further two months. In these cases they considered the severity to be proportional to the degree of exposure to chemical irritation by dust and fumes. Ninety had chemical nasopharyngitis and/or tracheobronchitis. This latter type of illness developed predominantly among furnace-workers.

The laboratory investigations were unremarkable. The erythrocyte sedimentation rates were essentially normal, and blood counts and blood chemistry were also normal. Tubercle bacilli have not been found (Van Ordstrand *et al.*, 1945). Reports on the morbid anatomy consist of five cases described as a typical pneumonitis (Van Ordstrand *et al.*, 1945). The salient features appear to be grossly heavy lungs (1,100–1,380 g.) with diffuse pulmonary oedema and haemorrhagic extravasation, considerable plasma-cell infiltration with a relative absence of polymorphonuclear cells, and some evidence of organization.

Treatment is symptomatic, with both penicillin and the sulphonamides being useless (Van Ordstrand *et al.*, 1945). Complete bed rest is regarded as essential, and no work should be permitted until all signs and symptoms of the disease have disappeared and the x-ray appearance of the lungs has returned to normal.

In the delayed form of the disease 17 cases of delayed chemical pneumonia were reported by Hardy and Tabershaw (1946) and Hardy (1947). Four of these came on while the patients were still exposed to beryllium after periods of exposure varying from eight months to five years. Two of these died. The remaining 13, four of whom died, developed symptoms from three months to three years after cessation of exposure to beryllium. Of the survivors only one is regarded as cured. Pascucci (1948), in his follow-up of the 11 survivors, found 30% dead and the same proportion *in statu quo*. The interval between exposure and the onset of symptoms may be as great as six years (Wilson, 1948). Agate (1948) has described a case in which the chest radiograph at first suggested miliary tuberculosis.

Discussion

On admission and for the first few weeks of observation this case was considered to be miliary tuberculosis; and, though the patient was afebrile, felt remarkably fit and well, and had only a slightly raised erythrocyte sedimentation rate, the x-ray film of the lungs on July 7 certainly seemed to confirm the diagnosis. However, the subsequent course of the illness as shown by serial radiographs rendered the diagnosis of miliary tuberculosis unlikely. Not only had the lungs cleared radiologically in eight weeks without streptomycin treatment but they had cleared completely without any residual fibrosis.

Eosinophilic lung is unlikely with only 500 eosinophils per c.mm. in the white count and the absence of bronchial spasm.

Ascariasis remained a possibility, but stools were free from ova when examined one year later, at which time they might well have been expected to be positive had the original infection been due to roundworm larval migration.

Miliary changes of similar distribution to those of miliary tuberculosis can occur in sarcoidosis, but though they may clear completely they take three to ten years to do it. They also tend to fluctuate over a period of months or years and are often accompanied by changes in other structures.

Pneumoconiosis is ruled out by the occupational history, the mycoses by the examination of the sputum, and carcinomatosis by the recovery of the patient.

It is of interest that the x-ray changes simulating miliary tuberculosis have not previously been described in the acute form of the disease but have been seen in the delayed type. The symptoms antedated the x-ray changes by about three weeks, but they cleared completely after eight days, at which time the x-ray miliary appearance was at its maximum. The x-ray changes subsequently persisted for a further two months in spite of the apparent well-being of the patient.

It seems possible that this man's illness was due to his contact with beryllium.

Summary

A case presenting clinically as a bronchiolitis occurring in a man handling fluorescent powders containing beryllium is described.

The x-ray changes were miliary in character and completely cleared in eight weeks without residual fibrosis.

The patient made a complete recovery.

The literature is briefly reviewed.

I am indebted to Dr. H. Jowles, at whose suggestion the diagnosis was made, to Dr. T. R. Riley for his reports on the earlier x-ray films, and to Dr. G. Doel for his reports on the later ones. I wish also to thank Dr. C. A. Birch for permission to publish this case.

INFECTIVE HEPATITIS AND PORTAL CIRRHOSIS

BY

K. DAMODARAN, M.B., B.S.

Major, R.A.M.C.

[WITH PHOTOGRAPHIC PLATE]

This paper is based on the clinical findings in 550 cases of infective hepatitis and necropsy findings in 22 fatal cases in different stages of hepatitis occurring in various theatres of war. The clinical types, signs, symptoms, pathology, and complications were discussed in two previous articles (Damodaran and Hartfall, 1944; Damodaran, 1948). The present paper is mainly concerned with the course of infective hepatitis and its sequelae.

Infective hepatitis, as already shown, causes a diffuse inflammation of the hepatic cells, varying from mild cloudy swelling to frank necrosis. Complete resolution takes place in a few weeks in the majority of cases. In a small proportion, however, fibrous-tissue reaction occurs in the portal spaces, producing various degrees of cirrhosis. The hepatic cells show different stages of necrosis, which is more advanced in the central zones of the lobules. This centrilobular zonal necrosis becomes apparent only at the later stage of the disease, approximately at the end of the second week. Round-cell infiltration is pronounced in the early stages, especially in the portal tracts. In later stages cellular infiltration diminishes and is almost confined to the periphery of the lobules, unless there has been an acute exacerbation or relapse.

Fig. 1 (Plate) shows the picture of the liver in the second week of the disease. The section was taken from the liver of an Indian soldier who died of fulminating infective hepatitis. Note the intense infiltration by round cells, most marked at the periphery of the lobules. The hepatic cells are in the early stage of necrosis. These changes were seen diffusely throughout the liver. The only other organ affected as seen at necropsy was the kidney. Fig. 2 (Plate) shows the swollen glomerulus with a few bile-pigment granules.

FIG. 5.—Liver $\times 50$. Centrilobular necrosis Third week.

The accompanying Fig. 5 shows centrilobular necrosis in the third week of the disease. The section was taken from the liver of a British soldier who died at the end of the third week. Cellular infiltration is scanty. The centrilobular necrosis is not uniform throughout the liver. Fig. 6 shows another part of the same liver. Note the advanced necrosis. The lobular architecture of the liver is completely lost. This advanced necrosis corresponded to paler areas of the liver seen macroscopically. Early fibrous-tissue proliferation at the periphery of the lobules is noted in some sections.

As the lobular pattern of the liver is distorted during the course of infective hepatitis fibrous tissue grows irregularly when healing takes place, without preserving the normal lobular architecture. It thus encloses multiple lobules as well as portions of lobules, giving the picture of portal cirrhosis. This was well illustrated in the previous paper (Damodaran, 1948).

Post-arsenical Hepatitis

The effect of hepatotoxic substances like alcohol, arsenic, and gold on infective hepatitis was described in detail by Damodaran and Hartfall (1944). Their observations agree with the findings of Borensztejn (1948), who described 216 cases of hepatitis in a Polish venereal disease treatment centre in Germany in 1946-7; 65% of his cases occurred during the peak months of October, November, and December. This figure exactly fits in with the findings in Malta during the siege. Note the high incidence of the disease during the months of October, November, and December. Unless this epidemiological finding is borne in mind one is likely to ascribe the fall in incidence after December entirely to the various prophylactic measures adopted to combat the disease. Ten of Borensztejn's cases of post-arsenical jaundice occurred so early in the course of treatment that the theory of syringe transmission is ruled out.

FIG. 6.—Liver $\times 50$ Diffuse necrosis. Third week.

He ascribed them to toxic hepatitis due to arsenic—in other words, arsenic-precipitated jaundice. These cases cannot be attributed to the toxicity of arsenic alone, as the incidence of jaundice is negligible during massive arsenotherapy for syphilis (1,200 mg. of "mapharside" in five days). The most significant finding is the difference in mortality between post-arsenical jaundice and jaundice not treated with arsenic. In the former the mortality was 30.8%, whereas in the latter it was less than 3% in the same clinic.

This illustrates the effect not only of arsenic but of all other similar hepatotoxins on the severity of infective hepatitis if administered during the incubation period, as shown before (Damodaran and Hartfall, 1944).

The histological appearance of the liver in post-arsenical hepatitis is the same as that in infective hepatitis, both in the early and in the late stages. Fig. 7 and Fig. 3 (Plate) show the late sequelae of post-arsenical hepatitis. The sections were taken from the liver of a British soldier who died five years after the initial attack of hepatitis. He developed jaundice after completing five courses of arsenic treatment for syphilis in October, 1943. Penicillin followed by arsenic was given in 1947 for a fresh attack of primary syphilis. Jaundice developed after the tenth injection of

FIG. 7.—Liver $\times 80$. Post-arsenical hepatitis with cirrhosis. Late stage

arsenic. He was treated in hospital for two and a half months and was discharged after the jaundice had cleared up. Two months later he relapsed without any obvious cause: bilirubin, 14 mg. per 100 ml.; colloidal gold, 555532; thymol turbidity, 12 units; plasma proteins normal. He died a fortnight after admission. Note the marked cirrhosis, the cellular infiltration, and the islet of liver parenchyma enclosed by fibrous tissue.

It seems that in this case the liver never completely recovered from the effects of the first attack of hepatitis in 1943. The second course of arsenic, in 1947, brought about jaundice, which cleared up under treatment. The liver, however, did not recover completely, but progressed to cirrhosis. Hepatic failure gradually set in.

Portal Cirrhosis

A case of hepatitis sine icterus progressing to portal cirrhosis was described in the previous paper (Damodaran, 1948). I came across three similar cases in a military hospital in India in 1946. All these patients were teetotallers

and non-vegetarians—two Hindus and one Moslem. The cases were fully investigated to rule out any other possible diagnosis. They were treated with high protein diet for two to three months, but there was no evidence of any improvement. Two of them were finally invalided out because of portal cirrhosis. The condition of the other patient gradually deteriorated. He developed progressive jaundice and ascites and was tapped a few times. He died in coma due to hepatic failure four months after admission to hospital. Necropsy showed typical portal cirrhosis as illustrated in Fig. 4 (Plate) and Fig. 8. Note the round-cell infiltration in the portal tracts.

These three soldiers had been on normal well-balanced Army diets for two to three years before they developed cirrhosis. A nutritional factor has thus been eliminated. Besides, dietetic treatment had no effect on the course of the disease, though given early enough. Infective hepatitis was prevalent among the Forces at that time. Still, it was possible to doubt whether these cases were really hepatitis sine icterus progressing to cirrhosis: so I decided to investigate whether cirrhosis could be present in an isolated area affected by infective hepatitis. I visited a small village 500 miles away where infective hepatitis was known to be prevalent, and found one case of subacute necrosis, one of infective hepatitis which progressed to portal cirrhosis, and one of portal cirrhosis with ascites. The association of infective hepatitis, subacute necrosis, and portal cirrhosis is not a chance coincidence.

The course of infective hepatitis and its sequelae can be indicated as in the accompanying diagram.

Resolution is the usual result in the vast majority of cases. Acute necrosis occurs in from 0.2 to 1.5% of cases. Subacute necrosis occurs slightly more frequently. It is not

canaliculi are also obstructed owing to the swelling of the cells, and jaundice develops. Cellular infiltration is scanty in the central zones of the lobules because the blood supply is diminished, blood being diverted into newly opened channels.

The severity of the disease depends on the diffuseness of the lesion. If all the liver cells are affected the organ will be knocked out early, even before histological changes become apparent. When the liver is so inflamed one can imagine what effect hepatotoxins would have on it. They would not only precipitate jaundice in hepatitis

sine icterus but would bring about acute or subacute necrosis as well. A therapeutic dose of arsenic, gold, or carbon tetrachloride would leave the normal liver undamaged but would have a synergistic necrosing effect on the liver already damaged by infective hepatitis. The significance of this would be better realized if we recognized that infective hepatitis could exist without jaundice.

Fatty change is not a prominent feature of the liver in acute infective hepatitis or in the subsequent cirrhosis except in chronic alcoholics. Experimental cirrhosis in animals is accompanied by significant fatty change in the

FIG. 8.—Liver $\times 30$. Late stage of hepatitis sine icterus. Portal cirrhosis.

possible to estimate what proportion of cases develop cirrhosis.

Jaundice may or may not appear during the course of the disease; or it may appear in the beginning, middle, or towards the end.

Discussion

For a long time the sequelae of infective hepatitis remained obscure because there was no correlation between the clinical and pathological findings. The histological appearance of the liver is so different in various stages of the disease that the pathologist considered these as separate diseases. Acute and subacute necrosis of liver are in fact only fulminating and severe types of infective hepatitis.

The hepatic cells are inflamed diffusely, but consideration of the architecture of the liver lobules shows that the central zones are the most vulnerable part and so naturally suffer most. Though there is a double blood supply, there is only one outlet through the intralobular (central) vein. In the acute stage there is not only round-cell infiltration in the portal tracts but also diapedesis of red blood cells showing congestion. The sinusoids are narrowed owing to swelling of the liver cells, and so the outlet is partly obstructed. The unnamed minute vessels in the diaphragm are opened up as a result, establishing communication between the sinusoids and the right lateral thoracic vein. The latter vein is seen distended in some severe cases. The bile

liver. There is no evidence to show that deficiency of proteins and vitamins has any aetiological significance in infective hepatitis and subsequent cirrhosis. The cirrhosis described in African pellagrins by Gillman and Gillman (1945) seems to resemble haemochromatosis rather than classical Laennec's cirrhosis. It is preceded by pronounced fatty change.

The external appearance of the liver may vary at different stages: in the early stage it is smooth; later it appears finely granular; and in the final stage it is grossly nodular and somewhat atrophic.

Liver-function tests are occasionally unreliable in assessing the damage done to the liver. Serum from the patient the section of whose liver is illustrated in Fig. 5 gave normal results for serum colloidal gold, thymol turbidity, Takata-Ara, and serum alkaline phosphatase tests two days before his death and again on the day he died. In the case illustrated in the accompanying Fig. 7 and in Fig 3 (Plate) all tests done were positive before the patient died. The tests in both cases were made in the same laboratory. The severity of the cases could be assessed more accurately by clinical examination alone.

Treatment

In no other disease has the treatment so much changed from time to time, according to the prevailing views on the pathogenesis of the condition, as in infective hepatitis. Daily

purgatives and lacto-vegetarian diet were the basis of treatment in the past, when a mucous plug in the ampulla of Vater and catarrhal inflammation of the bile ducts were thought to be the cause of jaundice. Duodenal intubation and lavage with magnesium sulphate solution were tried for the same reason. After animal experiments deficiency of proteins and vitamins was blamed, patients were put on high protein diet and massive doses of methionine, cystine, and vitamin B complex. Miraculous cures were claimed for protein hydrolysates and plasma transfusion. Equally miraculous cures have resulted from transfusion of glucose-saline. Rapid improvement has also been reported due to direct irrigation of the biliary tract with saline during laparotomy. When good results are claimed for such widely different treatments none of these can be specific. The assessment of the value of any form of treatment is exceedingly difficult owing to the natural tendency of the disease towards spontaneous cure. It is only when large numbers of patients have been treated that inefficacy of certain methods can be proved.

The liver has a marvellous capacity for recovery and regeneration. In the acute stage, when the liver cells are inflamed, rest to the organ is indicated more than anything else. Glucose, liberal fluids, and mild laxatives are beneficial. The diet should be light, low in fat, but otherwise balanced. The patient can leave the bed soon after the urine becomes bile-free.

In venereal disease treatment centres extreme care is essential for the prevention of post-arsenical hepatitis. Besides care in sterilizing syringes and needles, each patient receiving injections should be carefully examined before injection. Malaise, nausea, urobilinogen in urine, a trace of bile, or dark urine are all contraindications to arsenical treatment. If arsenic is given after the urine has turned dark, acute necrosis is likely to result. In relapse cases arsenic should be given up for good.

Once cirrhosis is established there is nothing at our disposal to prevent its progress. All that can be done is to prevent the surviving hepatic cells from degeneration. Restricted activities, well-balanced but low-fat diet, and glucose are helpful. All hepatotoxins should be scrupulously avoided. Ascites should be tapped if there is considerable fluid. Anaemia should be treated with iron and liver extracts. If bleeding occurs vitamin K should be injected. All measures to improve general health should be taken.

Morphine is not advisable even in small doses in cholaemia of acute necrosis and late stages of cirrhosis. Even $\frac{1}{4}$ gr. (8 mg.) of morphine is likely to cause fatal coma in a severe case. If delirium is present and insomnia is troublesome, 4 dr. (15 g.) of paraldehyde should be given in saline by rectum and repeated as necessary.

Summary

The course of infective hepatitis and its sequelae are described. Post-arsenical hepatitis is discussed. The development of portal cirrhosis is traced from its source—hepatitis sine icterus. The association of infective hepatitis, subacute necrosis, and portal cirrhosis in areas where infective hepatitis is prevalent is not a chance coincidence. A clinico-pathological classification indicating the course and sequelae of infective hepatitis is given. The mechanism of the production of centrilobular necrosis is discussed. The difference between Laennec's cirrhosis and experimental cirrhosis is stressed. The external appearance of the liver in different stages is described. The unreliability of liver-function tests in estimating the severity of infective hepatitis is demonstrated. Treatment is critically surveyed. Photomicrographs to illustrate the picture of the liver in different stages of the disease are given.

I wish to record my indebtedness to Professor S. J. Hartfall for his constant interest and encouragement. I am indebted to Colonel E. Underwood and Colonel D. Murray for permitting this work to be carried out. My thanks are due to Lieutenant-Colonel R. Kempthorne, Captain Krishnaswamy, Captain Bernstock, and Captain Dexter for valuable help. My thanks are also due to Mr. Dodds for the photomicrographs and to Privates Harry Castle and K. A. Pallister for help in procuring records and other material.

TREATMENT OF ABORTUS FEVER WITH SULPHONAMIDES AND BLOOD TRANSFUSION

BY

C. ROMER, M.B., B.S.

Medical Registrar, Worcester Royal Infirmary

Since the annotation in the *British Medical Journal* (1947, 2, 700) on the treatment of undulant fever by sulphonamides and blood transfusion two cases have been seen in which this new suggestion could be tried. (These are reported because of the satisfactory response to treatment and because of an interesting complication.)

Case 1

The patient, a youth aged 16, was in perfect health until the beginning of June, 1948, when he began to feel cold and had three attacks of shivering. A week before admission he developed gingivitis. On June 16 he woke up to find that he was blind in the left eye. He had had no pain and did not feel ill. Two days later he was admitted to hospital. His previous history and that of his family were not relevant. He was a farm labourer, spending most of his time with cattle. His employer had also been ill "with something similar," and it was subsequently confirmed that he too had had undulant fever. Bowels and micturition were normal. There was no loss of appetite or weight.

On admission his temperature was 103° F. (39.4° C.), pulse rate 112, and respiratory rate 28. He was flushed and was sweating profusely; nevertheless, he was emphatic that he did not feel ill. Gingivitis was present. His tongue and throat were normal. Blood pressure was 130/70. The cardiovascular, respiratory, and central nervous systems were normal. There was no enlargement of the spleen or liver, but slight enlargement of the cervical, axillary, and inguinal lymph nodes. There were a few macules on the arms and calves. Hess's test was negative. Vision in the right eye was normal except for a refractive error (hypermetropia); the pupil acted on accommodation and to direct light, but the consensual light reflex was absent. The left pupil was larger than the right, and it reacted neither on accommodation nor to direct light, although the consensual light reflex was present. The left eye had an internal strabismus (congenital) and was amblyopic. Ophthalmoscopy showed a recent thrombosis of the central retinal vein, and it was fortunate that it was in the amblyopic eye.

Abortus fever was considered a likely diagnosis for two reasons: the history of working with cattle, and the little discomfort associated with the marked pyrexia and sweating.

Investigations.—A blood count on June 18 showed: haemoglobin, 87% (13.5 g.%); colour index, 0.89; red cells, 4,920,000; white cells, 6,000 (neutrophils 3,600—band forms 720, segmented forms 2,880—lymphocytes 2,280, monocytes 120). An agglutination test on June 18 gave a positive reaction to both *Brucella abortus* and *Br. melitensis* in all dilutions from 1 in 20 to 1 in 5,120. Lumbar puncture on June 19 showed: pressure, 60 mm.; no block; approximately 5.5 ml. of clear colourless fluid; 1 cell per c.mm.; red cells, very scanty—cytology, lymphocytes only seen; protein, 18 mg. per 100 ml.; pandy, no increase; Lange, 100,000; Wassermann, negative; chlorides, 700 mg. per 100 ml. A blood culture on June 19, when the temperature was 103.6° F. (39.8° C.), gave a growth of an organism which was morphologically similar to *Br. abortus* and *Br. melitensis*. However, it refused to grow under aerobic conditions, but did so readily with an increased CO₂ tension. This indicated *Br. abortus*. Radiographs of the chest and skull on June 19 were normal. The urine was normal.

Treatment and Progress.—On June 24 he was given 1 pint (570 ml.) of fresh blood and 3 g. of sulphamezathine followed by 2 g. six-hourly. This was continued until July 1—total, 59 g. The pyrexia continued as shown on Chart 1, settling on a lower plane on July 3. A painful small effusion of the left knee developed on June 26 which disappeared four days later. Throughout, he said he never felt ill. The spleen was never palpable. He was discharged afebrile on July 17 after four weeks in hospital, or six weeks since the onset of the illness. He was seen again on Aug. 21 and Sept. 18, when he was

Chart of Case 1

in perfect health. In December he was reported to be still well. The left eye has remained blind.

A differential white count on July 2, after sulphonamide, showed: white cells, 4,100 (neutrophils 1,681—band forms 246, segmented forms 1,435—eosinophils 123, lymphocytes 2,091, monocytes 205).

Case 2

A married woman aged 46 was admitted on Jan. 17, 1949, the diagnosis of abortus fever having been made two weeks previously, the agglutination reaction being positive. She complained of pyrexia in the afternoons and evenings, with much sweating—sufficient to cause her to rise and change her night attire. Her previous history was as follows:

In October, 1948 (12 weeks before admission), she had "influenza." Her symptoms were identical with those described above, and she stated she had not felt well since, sweating having occurred on and off. This was evidently the onset. In December (six weeks before admission) the symptoms became worse, occipital headaches and ulcers in the mouth occurring for the first time. She had had a slight macular rash on the body the week before admission. No joint pains occurred. Her previous history and that of her family were not relevant.

Chart of Case 2

She had lost weight (no details available). The undulant nature of the fever is well shown in Chart 2, kept by her daughter. Both she and her husband worked in a Milk Marketing Board office but handled only milk return forms. They lived in the

country, the milk supply being direct from a farm and not pasteurized. There was no known contact. On examination her general condition was good, with no obvious loss of weight. She was sweating. The temperature was 99° F. (37.2° C.), the pulse rate 100. All systems were normal. The spleen was not palpable and there was no rash.

Investigations.—An agglutination test on Jan. 1 gave a positive reaction in a dilution of 1 in 1,280 to *Br. abortus*. A blood count on Jan. 18 (before transfusion) showed haemoglobin, 93% (14.5 g.%); colour index, 0.95; red cells, 4,920,000; white cells, 4,000 (neutrophils 2,320—band forms 1,240, young forms 40, segmented forms 1,040, eosinophils 80, lymphocytes 1,160, monocytes 440). A blood count on Jan. 27 (after transfusion) showed: haemoglobin 90% (14 g.%); colour index, 1; red cells, 4,510,000; white cells, 5,000 (neutrophils 2,000—band forms 650, segmented forms 1,350—eosinophils 500, lymphocytes, 2,000, monocytes 500). A blood culture on Jan. 17 gave a good growth of *Br. abortus* after seven days' incubation. A fractional test meal showed a low acid curve. This was done as it is remarkable that a milk-borne disease should be only sporadic, and it may be that individual susceptibility depends on failure of this first line of defence. The urine was normal.

Treatment and Progress.—On Jan. 19 she was given a blood transfusion of 1 pint (570 ml.) of fresh blood and 3 g. of sulphamezathine followed by 2 g. six-hourly until Jan. 24—total 47 g.

On Jan. 27, the day she left hospital and eight days after starting treatment, she became afebrile and has remained so ever since. When seen on Feb. 26 and March 25 (two months follow-up) she was in normal health.

Discussion

Two cases of abortus fever (one having a rare complication) successfully treated with sulphonamides and blood transfusion is added to the two of Holmes and Hughes (1948). In Case 1 sulphamezathine and a single transfusion of 1 pint of fresh blood were used, beginning three weeks from the onset of the disease. Three weeks later the patient was discharged cured, and remained so. Holmes and Hughes used sulphadiazine and three small transfusions; their cases were treated eight weeks and six weeks from the onset, and were discharged after two weeks' treatment. This is encouraging in a disease which commonly has a long duration (Price gives an average length of three to four months; while Saville mentions three to six months). In the literature no reference to thrombosis of the central retinal vein in abortus fever has been found.

Although two swallows do not make a summer, and this treatment of abortus fever has been criticized by Professor Debono (1949), it seems only reasonable to conclude that the strain of *Br. abortus* met with in this country is sensitive to such treatment. The results certainly justify further trial.

My thanks are due to Dr. J. O. Terry, under whose care the patients were, and to Mr. I. Lloyd-Johnstone for his report upon the condition of the eyes in Case 1.

The annual general meeting of the Society for Relief of Widow and Orphans of Medical Men was held on June 1. Dr. Aliso Glover, a vice-president, was in the chair. The annual report and financial statement for 1948 was approved. At present the membership of the society is 250. Forty-six widows are in receipt of grants, and the total sum distributed during the year was £4,545. Income exceeded expenditure by £802 9s. 2d. It was decided that by-law 46 should be amended so that any widow whose annual income does not exceed £150 will be eligible for grants, as compared with an annual income of £125 as at present. The meeting concluded by passing a vote of thanks to Sir Robert A. Young, the president, for his services during the past year. Membership of the society is open to any practitioner living within a 20-miles radius of Charing Cross, and further details may be obtained on application to the secretary of the society, 11, Chandos Street, W.1.

TREATMENT OF HERPES ZOSTER WITH LIVER EXTRACT

BY

H. S. GASKELL, M.B., Ch.B.

Medical Officer, E. Stow, Suffolk

Although the eruption of herpes zoster may appear without discomfort, the pain associated with the condition is sometimes considerable; and post-herpetic neuralgia may occur with such severity and persistence that, as Osler (1898) recorded, it has been known to drive a patient to commit suicide. The treatments recommended have been legion, including iron, arsenic, strychnine, gelsemium, valerian, and aconite, as well as the customary analgesics; freezing, iniments, diathermy, and the injection of distilled water beneath the skin have also been used.

Dickie (1946) relieved herpetic pain in prisoners of war by use of injections of liver extract, which was the only drug available. I have since had the opportunity of observing the effect of liver extract administered empirically to 10 patients with herpes zoster. In all cases the preparation used was "neo-hepatex," administered intramuscularly.

Case Histories

Case 1.—June 19, 1946. Male aged 76. Herpes of left forehead, with severe pain. Dosage: 4 ml. The following day there was no pain and the lesion had not extended. A further 1 ml. was given the next day. There was no post-herpetic pain or recurrence.

Case 2.—July 20, 1946. Male aged 47. Herpes of forehead. Dosage: 4 ml. first day, followed by 2 ml. on the two ensuing days. Pain ceased after the first injection.

Case 3.—Oct. 2, 1946. Female aged 71. Herpes involving the twelfth thoracic segment on the left side, with severe pain. Dosage: Two injections of 4 ml., with three days' interval. Pain completely relieved by Oct. 7.

Case 4.—Oct. 3, 1946. Female aged 63. Herpes of left side of head and neck, with severe pain. Dosage: 4 ml. on Oct. 3 and Oct. 5. Completely free from pain after Oct. 5.

Case 5.—Oct. 4, 1946. Male aged 16. Herpes of right buttock and thigh, with moderate pain. Dosage: 4 ml. Pain and vesicles disappeared in 24 hours.

Case 6.—Oct. 14, 1946. Male aged 77. Complained of post-herpetic neuralgia for 10 months. Dosage: 4 ml., with relief of pain. A further 4 ml. was injected on Oct. 16.

Case 7.—Oct. 28, 1946. Male aged 68. Post-herpetic neuralgia for 15 months. Three injections of 4 ml. produced no diminution of pain.

Case 8.—Nov. 28, 1946. Male aged 38. Herpes genitalis for 6 weeks. Dosage: 4 ml. on two successive days. By Dec. 3 the herpes had disappeared.

Case 9.—Jan. 13, 1947. Male aged 23. Herpes of left chest, with moderate pain. Dosage: 4 ml. on three successive days. Pain-free on Jan. 16.

Case 10.—Jan. 14, 1947. Female aged 75. Three days' history of herpes of right thigh, groin, and lower abdomen, with severe pain. Dosage: 4 ml. on two successive days. Complete relief of pain.

Case 11.—May 5, 1947. Female aged 56. Herpes of right upper thorax, right shoulder, and neck, associated with severe pain. Dosage: 4 ml. on May 5 and May 6; 2 ml. on May 10. The pain became considerably less by May 8, and the patient was pain-free on May 12.

Case 12.—July 1, 1947. Female aged 59. Two weeks' history of herpes of forehead, with moderate pain. Dosage: 4 ml. on July 1 and July 2, with diminution of pain.

Case 13.—July 14, 1947. Male aged 66. Herpes of left face for a week. Dosage: 4 ml. on July 15, 17, and 19. Pain relieved after first injection. Pain-free by July 26.

Case 14.—Sept. 8, 1947. Male aged 34. Two days' history of herpes of left groin. Dosage: 4 ml. on Sept. 8, 9, 12, and 15. By Sept. 15 he was pain-free and the rash had faded.

Case 15.—Sept. 18, 1947. Female aged 26. Herpes of left face, with considerable pain and constitutional disturbance. Dosage: 4 ml. on Sept. 20. This had no effect on the condition, which cleared, however, by Oct. 9.

Case 16.—Sept. 24, 1947. Male aged 22. Herpes of left chest. Dosage: 4 ml. on Sept. 24 and 25, with relief of pain.

Case 17.—Dec. 1, 1947. Female aged 67. One week's history of herpes of upper right chest. Two days previously the rash had spread to the right side of the neck and face, and there was considerable pain and malaise. Dosage: 4 ml. on Dec. 1, 2, and 8. Pain lessened after the first dose and completely disappeared by Dec. 12.

Case 18.—Jan. 21, 1948. Female aged 31. Two days' history of herpes of the left chest, with pain. Dosage: 4 ml. on Jan. 21. Pain-free, with no further extension of the rash by Jan. 24.

Case 19.—July 10, 1948. Female aged 58. One week's history of herpes of the left side of the neck. Dosage: 4 ml. on the succeeding two days. Pain was relieved by July 12, and had completely disappeared by July 19.

Case 20.—Aug. 19, 1948. Male aged 73. One day's history of herpes of right hip and abdomen, with severe pain and malaise. Dosage: 4 ml. on Aug. 19 and 21, with relief of pain.

Medical Memoranda

A Case of Abortus Infection treated with "Aureomycin"

Spink *et al.* (1948) reported a series of 24 cases of human brucellosis due to *Br. melitensis* treated in Mexico with "aureomycin" (Lederle Laboratories). They say: "In such a disease a long follow-up study will be necessary to evaluate the drug completely. . . . But the immediate results of treatment have been so encouraging and so unexpected that this report is being made." The following is an account of a case of *Br. abortus* infection in which the immediate results were striking also.

CASE REPORT

The patient, a man aged 58, became ill fairly abruptly in the middle of February, 1949, at a time of influenza prevalence. The persistence of the illness led to its differentiation from influenza, and a blood agglutination reaction on March 16 gave a titre to *Br. abortus* of 1:500, less decisively 1:1,000. At this time the pyrexia was mainly at night, and often there was a night sweat. He was given 36 g. of sulphamezathine over six days without effect. The pyrexia next became diurnal also and the number of sweats increased to several in a 24-hour period. At this stage he was admitted to hospital on March 28, about six weeks from the onset.

His general condition was comparatively good, but he was anxious about his apparently interminable, uncomfortable, and incapacitating illness. Clinical examination did not reveal anything inconsistent with brucellosis: no enlargement of the spleen was detected. Agglutination reactions again gave 1:500 to *Br. abortus*, and blood culture was negative. An issue of streptomycin was obtained, but no apparent effect from the drug was noted with a dosage of $\frac{1}{2}$ g. intramuscularly every six hours, and after five days the drug was stopped. Two days later aureomycin was started by mouth and given as follows: one capsule (250 mg.) every twelve hours for two days and two capsules (500 mg.) every six hours for $7\frac{1}{2}$ days (a total of 16 g.

of drug). The initial smaller dose was to minimize any tendency there might be to a sharp reactive rise of temperature on beginning treatment—a tendency reported in the series of Spink *et al.*

After starting the drug the pyrexia, which had been broadly of an intermittent pattern swinging between limits of 97 and 102° F. (36.1 and 38.9° C.), became in about 24 hours more continuous and reached over 103° F. (39.4° C.); in a further 36 hours it began to fall rapidly and reached normal in about another 24 hours, where it remained. It was still steadily normal 10 days later, when the patient's wish to return home was acceded to (April 22), and on interviewing him on May 12 he reported continued freedom from his former febrile sensations, and a single check on his temperature gave a normal level.

The drug was easily administered and caused no apparent toxic reactions.

I am indebted to Dr. R. E. Jones, of the Public Health Laboratory, Coventry, for serological data and other assistance, and to Dr. T. H. W. Ritchie, of Bedworth, Warwickshire, for clinical information.

Arteriovenous Fistula of the Lung

[WITH PHOTOGRAVURE PLATE]

Until recently arteriovenous fistula of the lung has only rarely been reported. It was thought worth while, therefore, to record the following case, with details of the investigations made to establish the diagnosis. The question of the advisability of surgical treatment in this case is discussed.

CASE REPORT

The patient, a man aged 36, first came under medical care in August, 1947, complaining of a dull ache in the right upper chest which he attributed to strenuous and unaccustomed exercise taken some two weeks before. There was a history of slight morning cough for some years, with an occasional trace of mucoid sputum, in which he had noted streaks of blood once only, on the day before he was first seen. This streaking has since been observed on another occasion. No dyspnoea or other symptoms have been present. His previous history was not relevant, and on close questioning epistaxis or other evidence of a bleeding diathesis was not admitted. Goldman (1948), in a review of the literature, has stressed the hereditary factors in the aetiology of the condition, but in this case the family history, so far as it could be obtained, was also negative.

Physical examination did not reveal any cyanosis or finger-clubbing, and no abnormal physical signs were found in the respiratory system. The pulse was regular at 80 per minute and was not collapsing in character. There was no evidence of enlargement of the heart or of cardiac murmurs. The blood pressure was 135/75 mm. Hg in both arms. A soft murmur, heard only in systole, was present over a roughly circular area about 6 in. (15 cm.) in diameter in the lower part of the right axilla. The murmur was faint but could be well heard with the patient lying on his left side and extended over a pillow. It was not appreciably affected by respiration. Careful examination of the skin and mucous membranes revealed no evidence of other haemangiomas or telangiectases. Other systems were normal.

The diagnosis was chiefly established by radiography. The postero-anterior film (Plate, Fig. 1) showed a mottled opacity in the lower zone of the right lung which on the lateral film overlay the lower part of the heart shadow. Between the opacity and the vascular markings of the right hilum was a longitudinal shadow which on tomography (Fig. 2) could be clearly identified as consisting of two main parts representing

branches of the pulmonary artery and vein. On screening, opinion was divided on whether the shadow pulsated, but it was noted in a bronchogram (Fig. 3) that, whereas nearly all the bronchial shadows, including those in juxtaposition to the heart, were present and clearly defined, those close to the main opacity were blurred.

Mr. R. C. Brock kindly arranged for angiography at Guy's Hospital, and the resulting radiograph (Fig. 4) leaves no doubt regarding the vascular nature of the lesion. Mr. Brock also reported a normal bronchial tree on bronchoscopy.

Blood examination revealed: red cells, 6,100,000 per c.mm.; haemoglobin (Haldane), 110%; white cells, 6,000 per c.mm., with a normal differential count. Oxygen saturation was found to be 89% in a specimen of arterial blood. The sedimentation rate was 2 mm. in one hour (Westergren). Culture of sputum revealed a mixed growth of normal pulmonary flora. The vital capacity was 4,500 c.cm. The electrocardiogram (three standard leads) was normal in all respects.

The case has now been observed over a period of seven months without any change in the clinical or radiological picture.

DISCUSSION

On the data available the lesion must be regarded as a vascular abnormality or tumour in the substance of the lung, with a minimal pulmonary arteriovenous shunt but no evidence of similar lesions or telangiectasia elsewhere though the presence of such lesions cannot be excluded *ante mortem*. In view of the minimal shunt in this case the possibility of the systemic (bronchial) circulation being implicated, as suggested by Maier *et al.* (1948), must be considered. The main practical problem is whether surgical removal should be advised. On the one hand we are dealing with a virtually symptomless lesion with very little disturbance of the normal physiology. On the other there is the danger of haemorrhage and the possible extension of the lesion with an increase in the shunt or even malignant change. At the moment there would appear to be no general contraindications to surgery, but from the few reported cases it would seem that operative removal is not without risk, particularly where there is a large pulmonary arteriovenous shunt. There is also no certainty that other lesions are not present.

Surgical removal has been advised but so far refused so that pathological data on the nature of the lesion are not available.

I would like to thank Dr. F. H. Young, physician to the Brompton Hospital, for permission to publish this case and for his helpful criticism; Dr. F. Prime for performing the oxygen saturation test; and Dr. L. G. Blair for the skiagrams.

F. D. BEDDARD, M.B., B.S.,
late A.R.M.O., Brompton Hospital.

Maier, H. C., *et al.* (1948). *J. thorac. Surg.*, 17, 13.

At a meeting of the Professional and Technical Council B of the Whitley Councils for the Health Services on April 20 the following agreement was reached on the salaries of medical laboratory technicians employed in the National Health Service in England, Wales and Scotland. *Student and Junior Technician*: Aged 16, £110 p.a. annum; 17, £125; 18, £145; 19, £165; 20, £195; 21, £225; 22, £240 10s.; 23, £260; 24, £279 10s.; 25 and over, £299. On passing the Intermediate Examination of the Institute of Medical Laboratory Technology (or equivalent qualification), or the Inter. B.Sc., the salary is increased by £13 per annum at any point on the scale. If no examinations are passed, the salary is increased to £312 per annum at age 30. *Technician*: £370-£435. On gaining the Fellowship of the Institute of Medical Laboratory Technology (or equivalent qualification) the salary is increased by £15 at any point on the scale. *Senior Technician*: £450-£530. *Chief Technician*: £530-£650. London weighting: In the Metropolitan Police Area all scale are subject to London weighting on the following basis: Age 16-20 £10; 21-25, £20; 26 and over, £30. The new scales operate from April 1, 1949.

Reviews

INFECTIOUS DISEASES

Traité de Médecine. Vol. I. Maladies Infectieuses. By A. Lemierre, Ch. Lenormant, P. Pagniez, P. Savy, N. Fiessinger, L. de Gennes, A. Ravina. (Pp. 1,096. 2,200 francs.) Paris: Masson et Cie. 1948.

The Acute Bacterial Diseases. By H. F. Dowling, M.D., F.A.C.P. (Pp. 465; illustrated. 32s. 6d.) London and Philadelphia: W. B. Saunders. 1948.

These two books cause one to reflect on the needs of the reader of the textbook on infectious diseases. Some will want a work which devotes special care to the description of all aspects of the infections, a book to which reference can be made when the unusual is encountered and which will reflect the breadth of the writer's experience. Such is the clinician's book, and after the detail of the clinical description the reader is satisfied with less in the way of bacteriology, pathology, epidemiology, or even specific therapy. This is the classical approach, and the original texts of books like Ker's *Infectious Diseases* and Ricketts's monograph on smallpox still remain as up to date as when they were written because of the mastery they display in their clinical observation. Others, however, will be content if the clinical descriptions are less detailed, provided there is adequate discussion of the most recent knowledge of, for example, bacteriology or therapy. Naturally, this type of book tends to "date" more quickly, especially in these days, when treatment may change so rapidly.

Either of the present books may be recommended to both groups of readers, though each has its emphasis towards one or other aspect of its subject. The French work tends towards the classical form. The present volume is the first of a series of seventeen which will clearly supply a comprehensive review of modern French medicine. The infectious diseases described comprise most of the notifiable diseases common to this country. A detailed clinical description is supplied; and, as one would expect in a Continental textbook, each disease is carefully subdivided into every possible clinical type. There is no doubt that the book excels in painting the clinical picture, and though the British reader will not agree with all the interpretations he will enjoy the reading.

The section on typhoid fever (which occupies 164 pages) may be used to exemplify the style. The bacteriological description is impoverished by an absence of reference to recent advances, and the importance of phage typing is not mentioned. This naturally weakens the section on epidemiology. The discussion of pathogenesis is excellent; so is the detailed description of the clinical course of the disease and its treatment. Here, as elsewhere, the fine subdivision into different clinical types rather engenders the view that "the disease is everything." One would welcome an extended discussion on the host-parasite relationship and a more obvious appreciation that the form of the infection is not merely a question of the causative organism.

Scarlet fever is excluded from the section on streptococcal diseases and is described as a specific malady, the writer agreeing with the Dicks on the specificity of the scarlet fever streptococcus. There is thus no concept of scarlet fever as but part of the whole range of streptococcal disease. The role of re-infection as a causative factor in many of the complications is not stressed, and the possible connexion between scarlet fever and rheumatic fever is overlooked. Finally, one notes that the use of laboratory methods in the diagnosis of smallpox is not well discussed and the place of egg-culture not mentioned. But these deficiencies, viewed from the classic approach, are secondary to the excellence displayed in the description of the disease.

Dowling's book, as one would expect, is a praiseworthy survey of the "new look" in fevers. Here the author turns away from the strictly clinical or pathological approach, and, because of the importance of the aetiological agent in dictating treatment, groups the diseases on a bacteriological basis. There is thus particular emphasis on the place of laboratory aids in obtaining a precise diagnosis. Having decided on the most rapid and certain methods to be used, the author discusses

specific therapy and the effects which may be expected from its correct application. In the first part of the book are four chapters dealing with serum therapy, sulphonamides, penicillin, and streptomycin. These present a clear review of the subjects and should be particularly valuable to the person who is not dealing with these substances daily in infectious diseases, for they are essentially practical. Throughout the book there is a profusion of practical diagrams and individual case records, permitting the reader to see how his case ought to respond to the treatment advised. Though it is somewhat expensive for the student, there can be no doubt that the practical tone of the book and its ready appeal to the visual memory make it a useful volume for the undergraduate. The graduate can be assured of finding in it a fund of ripe experience.

T. ANDERSON.

STUDIES IN NEUROLOGY

Critical Studies in Neurology. By F. M. R. Walshe, M.D., F.R.S. (Pp. 256. 15s.) Edinburgh: E. and S. Livingstone. 1948.

In this convenient little volume Dr. Walshe reprints some of his well-known contributions to neurological literature. He excels at writing a critical review, and the reader cannot fail to admire his remarkable clarity of thought, choice of words, and vigour of expression. Six of his studies are reprinted, including those on cutaneous sensibility, the motor cortex, and the pyramidal system, as well as his address on the integration of medicine.

A prime purpose of this reprint is "to stimulate critical thinking amongst postgraduate students." While some knowledge of recent neurophysiological and anatomical work is desirable for the full appreciation of Dr. Walshe's reviews, students in many branches of medicine will welcome this collection of his stimulating studies.

W. RITCHIE RUSSELL.

AGONAL ACIDOSIS

Investigations on Agonal Acidosis. By I. B. Fabricius Hansen. (Pp. 134. No price.) Copenhagen: P. Branner, 29, St. Kongensgade. 1948.

This monograph is the result of an elaborate study of blood chemistry in 38 cases of impending death. Particular attention was paid to changes in acid-base balance, and known causes of acidosis, such as diabetes and nephritis, were excluded from the series. The author concludes that a profound acidemia is a frequent finding in the agonal state, the value of the blood pH falling to 7.0 or lower. This acidosis is partly due to organic and inorganic acids—lactic, pyruvic, phosphoric and sulphuric—but decreased pulmonary ventilation is a contributory factor, causing a rise in the CO₂ tension of the blood. Azotemia is also usually present, but is not directly correlated with the acidosis.

A possible criticism of the results lies in the method of blood sampling, which was by venesection or by cardiac puncture after death. Arterial blood would have been more appropriate for these studies. This difference would, however, probably not invalidate the general nature of the results. The relation of the findings to therapy is discussed, and a case is recorded in which an apparently moribund patient was revived by treatment with nikethamide and ephedrine. On the whole the results recorded are those which might have been expected from previous work, but this well-documented account forms a valuable record of the nature of pre-mortal changes in blood chemistry.

N. F. MACLAGÁN.

GROUP THERAPY

Introduction to Group-Analytic Psychotherapy. Studies in the Social Integration of Individuals and Groups. By S. H. Foulkes, M.D. (Pp. 181. 21s.) London: William Heinemann Medical Books. 1948.

The author describes methods developed by him to deal with civilian out-patients when wartime demands, which could not be met by individual psychotherapy, forced psychiatrists to experiment with group techniques. These methods were later applied to military patients at Northfield Military Psychiatric Hospital, and after the war to patients at Bart's. What was originally expedient to meet a particular situation became, in

TREATMENT OF HEPATIC CIRRHOSIS

Cirrhosis of the liver is not a condition which physicians expect to cure. In fact, in a paper appearing elsewhere in this issue Damodaran states that once cirrhosis is established there is nothing at our disposal to prevent its progress. But the discovery of the importance of malnutrition in the pathogenesis of the condition has led to improvements in treatment. Since Patek¹ introduced the high-protein, high-vitamin regime in 1937 many reports have appeared on cases of hepatic cirrhosis treated on similar lines. With very few exceptions these confirm Patek's favourable results. In the majority of the cases the effect of treatment was assessed only on clinical grounds, but liver-function tests were occasionally employed. The objective evidence of improvement recently obtained by Beams and Endicott² is therefore welcome. They studied a group of fourteen patients on high-protein, low-fat diets, nine of whom received a daily supplement of 4.5 to 5 g. of methionine. In all the patients receiving the supplement the histological changes indicated a favourable response, while in only one of the other patients were significant histological changes noted after treatment. This paper is illustrated by excellent photomicrographs which clearly show the improvements described.

Two other methods of treating hepatic cirrhosis have recently been reported; these are directed more towards improving the symptoms than towards reversing the changes in the liver. Schemm and Layne,³ following the former's success in the treatment of the ascites of congestive cardiac failure by a high fluid intake and diet low in sodium and high in acid ash, have used similar methods in the treatment of cirrhosis. The result in nineteen of the twenty cases treated was complete clearance of the ascitic fluid. Even when the serum protein was low and the albumin-globulin ratio reversed, large amounts of fluid were successfully eliminated, and the authors conclude with justification that too much emphasis has been placed on the increased venous pressure in the portal circulation and on the "critical level" of the plasma albumin as causes of ascites. This conclusion, at least as regards the effects of serum albumin, is confirmed by the report⁴ that in three cases intravenous injection of albumin was without effect upon either the ascites or the urinary output. It therefore seems that the liver plays an important part in water metabolism apart from its effects upon the serum proteins and the portal circulation. The observation⁵ that parenchymal hepatitis is associated with a fall in the anti-diuretic agent normally present in the urine indicates a possible mechanism by which the metabolism of water is disturbed in hepatic disease. Adequate excretion of this anti-diuretic factor, probably of pituitary origin, may depend upon the integrity of the liver, and impairment

of liver function might therefore lead to excessive water retention.

The second method of treatment is directed towards the correction of the endocrine disturbance frequently associated with hepatic disease. The commonest manifestation of such disturbance is a tendency to feminization in the male, as shown by gynaecomastia and testicular atrophy. These symptoms, together with alopecia pectoralis, spider naevi, and palmar erythema, are probably the result of impairment of the normal hepatic mechanism for the inactivation of steroids.⁶ Since the B vitamins appear to be necessary for the inactivation of oestrogens but not of androgens,⁷ the latter will be more completely inactivated than the former in patients with the malnutrition that frequently accompanies chronic hepatitis. Rosenak, Moser, and Kilgore⁸ have therefore studied the effect of testosterone propionate on twelve cases of alcoholic cirrhosis. They gave 25 to 100 mg. three times weekly after the progress on routine therapy had been assessed. All of the twelve patients treated felt better, and in eleven of them improvement was also noted in some of the following features: body weight, loss of ascites, spider naevi, and palmar erythema. This treatment, however, did not affect the growth of body hair or testicular atrophy, though sexual vigour was improved. Some improvement in the results of liver-function tests was also observed. The authors, while admitting the possibility that the observed benefits may have resulted from an improvement in general health, considered that testosterone was a valuable addition to the routine treatment of these cases. Since an increase of the basophil granules of the liver cells has been observed both after high-protein feeding and after androgen administration⁹ there may be reasons other than those mentioned by the authors for adopting this method of treatment.

CONSULTANTS' TERMS

The Ministry of Health has now announced the terms and conditions of service for consultants and specialists in the Health Service, and the statement appears in the *Supplement* this week. These are the final terms formulated after discussions held during the last few months with the profession. Consultants and specialists will have an opportunity of considering the terms before July 5, when the Central Consultants and Specialists Committee and the Joint Committee successively meet to consider the views of their constituents. No one should sign a contract until the Joint Committee has expressed its opinion on the Ministry's statement.

The financial terms offered are substantially the same as those in the original proposals.¹ It will be noted that consultants appointed at the age of 31 or earlier are still penalized for their youth. It is questionable whether these terms adequately translate the Spens recommendations into present-day values, since the increase varies between about 13% and 10%. If allowance is made for the Government superannuation contribution of 8% the betterment factor is between 22% and 19%. The remuneration offered medical superintendents is unsatisfactory in that the proportion of their time devoted to administration is to be

paid for at the rate appropriate to lay administrative staff (unless they devote only a small proportion of their time to it); yet a medical man brings qualifications to the task that the layman does not, and he should be remunerated accordingly. The Ministry's document states that boards should try to reduce to a minimum the time given by medical staff to administrative duties, but if it is the Minister's intention to eliminate medical superintendents from the Service he should say so directly instead of putting forward terms which may indirectly have that effect.

It is doubtful whether the security of tenure of posts offered consultants is adequate. The document states that no period of tenure or of notice should be specified in the contracts, and consultants may consider the safeguards offered to be too slight. If he thinks that the hospital board is unfairly terminating his appointment, the consultant can send a statement of the facts to the Minister, who will obtain the views of the board and put the case before a professional committee. The committee may interview both parties. In the light of the committee's findings the Minister may confirm termination, or direct reinstatement, or arrange a third solution agreeable to the parties concerned. It would be preferable if the case were put before the professional committee before the board considered the matter, and undoubtedly the consultant ought to have the right to appear before this committee if he wishes to. The Minister has included a paragraph pointing out that the board has a moral obligation to assist the consultant to obtain comparable work elsewhere if reorganization threatens his displacement or the serious disturbance of his services. Less reassuring is the absence of any provision preventing boards from whittling down the number of sessions done by a part-time consultant.

Consultants will be unlikely to find these terms so unreasonable that they wish to reject them outright. If this is the case, then the committees representing consultants and specialists may advise general acceptance of the terms and conditions offered, leaving open the question of modifying this and that detail in the light of experience.

STREPTOMYCIN AND THE LABYRINTH

It has been known from an early stage in the trials of streptomycin that damage to the labyrinth is not infrequent after large doses of the drug. A recent study by Barr, Floberg, Hamberger, and Koch¹ has shown that a daily dose of less than 1 g. and a total dose of less than 60 g. carry a relatively small risk of vestibular damage provided there is no impairment of renal function. Where, however, the kidneys are damaged or, in cases with normal renal function, if the dose of streptomycin exceeds the above limits, the amount of the drug in the blood may rise to a concentration sufficient to damage the vestibular system. Thus these authors observed evidence of vestibular disturbances in 16 out of 26 cases receiving more than 60 g. The evidence that streptomycin may affect the hearing is less conclusive. In the majority of the cases where deafness occurred, the disease for which the drug was given may equally well have caused damage to the eighth

nerve. Nevertheless, streptomycin may occasionally damage the hearing. The site of damage to the vestibular system is still in dispute. Glorig and Fowler² considered their clinical studies showed that streptomycin injures the vestibular nerve peripherally. Floberg, Hamberger, and Hyden,³ using cytochemical methods, demonstrated on experimental animals that the localization of such injuries is both peripheral and central; they found definite changes both in the vestibular ganglion and in Deiter's nucleus.

It is not often that an undesirable side-effect of a drug can be turned to good account, but Fowler⁴ has used streptomycin as a specific neurotoxin to damage the vestibular organ in cases of vertigo unsuitable for other forms of treatment. In a preliminary trial, four patients suffering from severe attacks of vertigo due to Ménière's disease and not relieved by medical treatment were given 0.5 g. of streptomycin every three hours (4 g. per day). The total dose varied from 25 g. to 33 g. The effect on the vestibular system was checked by daily caloric tests according to the method of Hallpike.⁵ The results appear to have been uniformly successful: the attacks of vertigo were completely or almost stopped for at least five to nine months, and in three out of the four cases the hearing was unaffected. In the dosage employed streptomycin produced what amounted to bilateral vestibular nerve section: the patients lost all reaction to labyrinthine stimulation. Violent rotation caused no nystagmus, and even iced water syringed into the ear for five minutes produced no reaction. The effect on locomotion varied with the previous functional efficiency of the vestibule and the age of the subject: if the disease had caused slight damage to the labyrinth the immediate result of streptomycin administration was severe vertigo such as is seen after surgical ablation of the labyrinth. The older the patient the less perfect was the compensation which ultimately took place. Compensation, however, was never complete, and all the patients subsequently found difficulty in walking in the dark. It would appear that this method of treatment merits further trial; as Fowler points out, it should be limited to those patients under the age of 50 with Ménière's disease affecting both vestibules in whom medical treatment has failed. Where the disease is unilateral the destruction of the labyrinth by alcohol injection or ablation is still the method of choice.

EXPERIMENTAL INTERVERTEBRAL DISK LESIONS

It is now established that lesions of the intervertebral disk frequently cause low back pain and sciatica, and removal of the offending disk relieves these symptoms in a great many patients. Unfortunately this is not invariably the case; furthermore, spinal fusion has not been successful in relieving pain in patients whose symptoms persist after the removal of a prolapsed intervertebral disk. Haas¹ has shown experimentally that excision of the disk by an anterior approach will result in fusion of the adjacent vertebrae, and other workers^{2,3} have reported that lesions similar to those noted in hypertrophic spondylitis can be caused by similar less extensive operations. Key and Ford⁴ have recently produced intervertebral disk lesions by operations on dogs. They found that vigorous curettage of the disk space from the posterior approach did not lead to bony fusion between bodies of the vertebrae. The value of this procedure is therefore doubtful. Moreover, vigorous traction on the adjacent nerve root may be followed by

excessive fibrosis in this region, and the constant presence of adhesions around the nerve roots in the experimental animals suggests that this may be a cause of post-operative pain. As a result of these findings Key and Ford recommend that the disk should be carefully and gently removed, and that the posterior nerve roots should be protected from trauma.

These observers also found that unilateral protrusion of a disk will follow the surgical weakening of the annulus fibrosus on that side. The superficial portion of the wound so made heals over, but there appears to be no power of healing in the deeper part of the disk, probably because of its avascularity. In consequence a prolapse gradually develops. They even found it possible to produce a lesion of the intervertebral disk by puncturing the annular fibrosis with a needle. It is interesting to note that the animals subjected to this experiment were young, for in 1943 Findlay and Kemp⁵ described osteomyelitis of the second and third lumbar vertebrae with collapse of the intervening intervertebral disk in a 1-month-old child. This lesion followed an attempt at lumbar puncture in the presence of skin sepsis. Recently Bromley, Craig, and Kessel⁶ have reported in this *Journal* a case of osteomyelitis of the third and fourth lumbar vertebrae associated with partial collapse of the intervening disk. Four years previously, when the patient was 12 years of age, lumbar puncture had been performed while she was suffering from meningococcal meningitis. In children the short distance between the skin and the disk, the thin annulus fibrosus, and the protrusion backwards of the disk under tension when the back is flexed for lumbar puncture all render this structure vulnerable to both infection and prolapse following damage by a lumbar puncture needle. It is obvious, therefore, that great care should be taken in the performance of lumbar puncture in order to minimize the danger of a prolapsed disk.

ABSORBABLE HAEMOSTATICS

Surgeons have long been haunted by the spectre of haemorrhage from inaccessible vessels. Much has been done by good lighting and exposure of the field of operation to reduce this danger, and much can be done by local pressure maintained with patience for many minutes if necessary. But in the rare case, even in experienced hands, packs or haemostats have had to be left in wounds, prolonging the period of danger for the patient and of worry for the surgeon. If they are left for more than 24 hours there is grave risk of infection, while their removal may restart the haemorrhage. The arrival of absorbable haemostatics has abolished these dangers, and several surgeons have reported on their usefulness.

Of the four substances in use oxidized cellulose, fibrin foam, and gelatin sponge have been developed in the U.S.A., and calcium alginate is a British product. All appear to be very effective haemostatics, and comparisons of the first three have shown them to be about equal in this capacity.¹ Oxidized cellulose, however, has the disadvantages that it is highly acid and so inactivates thrombin and penicillin, and it does not adhere so firmly as does gelatin; moreover, it has to be sterilized chemically with bacteriological control. There appears to be little difference in the efficacy of fibrin foam and gelatin sponge, but fibrin is more complicated to use and to sterilize and is more easily broken up. Gelatin sponge, which can be sterilized by dry heat, is

inexpensive, non-antigenic, non-irritant, and does not inactivate antibiotics or thrombin. Its efficiency as a haemostatic has been shown by its use to cover actual defects in large veins² and for wounds of the heart.³ Large nephrotomy incisions, extending into the renal pelvis, healed well without leakage of urine after packing with gelatin foam.⁴ A further application of absorbable haemostatics is for packing large cavities which have rigid walls. A notable example is the use of gelatin foam in the pleural cavity after pneumonectomy.⁵ Provided too large amounts are not used, dogs and rats tolerate it well. It stabilizes the mediastinum and reduces greatly the amount of fibrinous exudate, and at the same time it does not interfere with repair. If infection is present the gelatin is rapidly liquefied and does not aid the infective process. This experimental work suggests that gelatin foam will have a valuable place in thoracic surgery.

Calcium alginate gauze has been shown to be a useful haemostatic in liver wounds in cats,⁶ and it has the merit that it can be sterilized by autoclaving. It appears to be well tolerated in the tissues, and no untoward reactions were observed. There can be little doubt that the use of these and other absorbable haemostatics will increase, especially for arresting troublesome haemorrhage.

MEDICO-SOCIAL WORK IN V.D. CLINICS

Now that gonorrhoea and syphilis are so amenable to treatment, at all events in their early stages, more social and epidemiological studies are being undertaken with the object of finding out how the venereal diseases can be completely eliminated. Before the recent war almoners and social workers were employed in only a few of the larger V.D. clinics, and most stress was laid on treatment as a means of reducing the incidence of V.D. During the war contact tracing became an accepted practice, especially after some highly trained American nurses showed what it could accomplish, and consequently many more patients attended the clinics. All patients must be impressed with the necessity for continuing treatment, and defaulters must be followed up. There is, however, much more in the V.D. problem than this. Why are people promiscuous? Where are they promiscuous? Where do the uninfected meet the infected? Why do they not report for examination and treatment? Why do they default? Macfarlane¹ has recently given answers to these and other questions in a report on the results achieved by a medico-social unit set up in connexion with the V.D. department at the Newcastle General Hospital. The unit consisted of an almoner with assistants, clerical staff, and three full-time and three part-time health visitors. An analysis of the records of 1,000 patients attending the department revealed the following facts: 82% received some assistance from the unit; 1,560 contacts were brought to examination, and of these 70% were suffering from gonorrhoea or syphilis or both; 74% of the 1,000 patients were married; public houses were far the commonest meeting-places. Personal factors leading to promiscuity included unhappy homes, criminal tendencies, poor to moderate intelligence, irreligion, ill use of leisure, drab lives, drinking, and poor moral fibre. Long-term plans for the reduction of V.D. must take these causes of promiscuity into consideration.

Defaulters are common in all V.D. clinics, and in Newcastle they are written to and visited. Of 3,478 defaulting women, 2,032 reattended as a result of 6,344 letters and 5,195 visits, and 70% of male patients responded to one or two communications. These figures indicate the amount of labour involved. The main reasons for default include

difficulty of leaving work, illness, domestic troubles, and irresponsibility: it is clear that an efficient medico-social unit can help patients to overcome some of these handicaps. Penicillin treatment is considered to have increased defaulting because it shortens the period during which signs and symptoms persist. Inadequately treated syphilitic patients are a danger to themselves and to the community, and Macfarlane thinks that when adequate treatment can be obtained without difficulty such patients should be compelled to complete their treatment.

There can be no doubt that education, particularly sex education, is likely to be the most effective single method of solving the V.D. problem. Stokes² considers that the object of sex education is "to place reason in control of emotion without emotion losing its colourful and revivifying vitality." In his opinion sex education should begin at an early age, and if the educators—parents, school-teachers, doctors, and clergymen—are themselves ill-equipped to give the necessary instruction they must be educated first. Since promiscuity is the most important cause of the venereal diseases, it seems unlikely that any method of control will eliminate them until people cease to be promiscuous.

VOLUNTARY SOCIETIES AND THE STATE

The place of a voluntary society in a democratic State is rather like that of a doctor in his practice—the better it does its work the more likely it is to find its occupation gone. Some voluntary associations are complaining that under the Health Act their work has been taken over by the Government and there is nothing left for them to do. They do not always appreciate the compliment the State has paid them, and they may be inclined to overlook that even in a nationalized service there are plenty of outlets for voluntary effort. The value of the personal touch in services which are likely to become more and more impersonal cannot be overestimated. As Lord Beveridge¹ has pointed out, a "good" society cannot be made without voluntary action for social advance, even in what he calls a "social service State."

The Earl of Cranbrook, a member of the Royal Commission on Population, was announced to speak on the report of that Commission at the annual meeting of the Family Planning Association on May 28, but, because of delay in the publication of the report, he gave instead an informative and amusing dissertation on the place of voluntary societies, of which, he said, he had learned a great deal while sitting on the Commission. He divided them into two overlapping groups—the propagandist and the functional. One of the earliest examples of the former was the society founded by Wilberforce to combat the slave trade. In the functional group the friendly societies were among the first. Lord Cranbrook admitted that sometimes the voluntary societies were the resort of fanatics—people in whose bonnets was such a buzzing that they could hear nothing else. But even fanatics, he said, had their purpose; by their countering influences they helped a man to keep in the middle of the road, avoiding both intolerance on the one hand and indifference on the other, and he said that if he had a son who was a research student he would counsel him to subscribe to an anti-vivisectionist society just to maintain his poise. He had recently visited Germany, where he was unable to find any voluntary societies, with the result that the sort of work which such societies did here, and pressure groups did in the United States, was done by the various political parties, so that everything became more and more a "party" matter. It is to be hoped that the tendency for local councils, which now

undertake so much of the work begun by voluntary agencies, to divide themselves into political groups will not have the same result.

Another advantage which Lord Cranbrook found in voluntary societies was that they gave earnest people an opportunity to put in "overtime" for the benefit of the community. Many local health authorities have tried as far as possible to give the old voluntary organizations a place in their schemes, both because the latter had the experience and also because the authorities could enlist "sweated" labour without any pricking of conscience. Many people were glad to continue voluntary service; it was not uncommon for volunteers to serve as drivers and attendants in ambulance services taken over by local authorities. Lord Cranbrook did not develop an idea which he left with his audience, that there might be a voluntary organization new to this country, which might incur as much odium as Wilberforce's and yet be as successful in getting its idea accepted—namely, a society which would endeavour to ensure that useful citizens did not grow into a useless elderly dotage.

CLIMATE AND RHEUMATISM

The effect of climate on the cause and development of rheumatic diseases has hitherto been judged mainly by popular impressions rather than scientific research, though some papers of interest based upon careful observation, especially on humidity, were published in the old *Journal of Balneology and Climatology*. A serious obstacle to research has always been the difficulty of finding observers and persons willing to be kept under strict experimental conditions for sufficient length of time. Recently, however, the subject has attracted attention in Sweden, and Edström and his colleagues¹ at the University of Lund have studied the effect of hot, dry climatic conditions on rheumatic patients over a period of six years. A hospital ward of two beds was equipped as a climatic laboratory with double walls and ceiling, so that temperature and humidity could be maintained at any desired level.

In this "laboratory" sixteen patients in a late stage of rheumatic fever and eighteen patients with rheumatoid arthritis have been treated, each of them for a period of about three months, during which they were not allowed to leave the ward for any purpose. The room was maintained at a temperature of 89.5° F. (32° C.) with a relative humidity of 35%; these conditions were found to be comfortable. The authors observed that the skin temperature of the extremities became higher and that peripheral vasoconstriction was changed to vasodilatation; the oxygen saturation of the blood rose from a level of 51% in a room at 68° F. (20° C.) to 82% in the special ward; the cardiac output of normal hearts was unchanged; and in most cases the calorie consumption and the basal metabolic rate were also unchanged. Cultures of the throat flora were taken in all cases, and β -haemolytic streptococci were present at the outset in eleven of the patients with rheumatic fever and thirteen of the patients with rheumatoid arthritis; in 22 of these patients the streptococci disappeared. This interesting observation supports the view that hot, dry climates may be of benefit in rheumatic diseases. The principal effects on the symptoms and signs of disease were lessening of peri-articular swelling, diminished pain and stiffness, larger appetite, and improved circulation. No tendency to recurrence after return to normal room temperatures was observed in any case. The results of this remarkable piece of clinical research are of value as a study in assistance in the treatment of rheumatism in practice.

MEDICAL SCHOOL IN JERUSALEM THE HEBREW UNIVERSITY'S NEW FACULTY

[FROM A CORRESPONDENT]

The Undergraduate Medical School of the Hebrew University of Jerusalem was formally opened by Sir Leon Simon, chairman of the Executive Council, on May 17, in the presence of the Prime Minister and other notabilities. The Hebrew University has had for many years full teaching faculties of science, arts, and agriculture, and before the war was planning a faculty of medicine.

A new hospital of some 300 beds was built on Mount Scopus together with laboratories for pathology, bacteriology, parasitology, and hormone and cancer research. Before teaching could be started it was necessary to enlarge the institutes of chemistry, physics, and biology, and to provide accommodation for departments of anatomy, physiology, and pharmacology. The war stopped progress along these lines and post-war disturbances slowed down the rebuilding programme.

At the end of the British Mandate and with the outbreak of Arab-Jewish fighting the university area was completely cut off from the Jewish part of Jerusalem and all work there came to a standstill. Fearing this development, the Jewish authorities had removed as much of the hospital and laboratory equipment as possible into the New City and had fitted up temporary accommodation. These makeshift hospitals cared for many thousands of sick and wounded in Jerusalem.

Among the volunteers who helped the Israeli Army during the fighting were medical students from many countries who had left their work at different stages in their curriculum and who, when the fighting ended, either could not or did not wish to return to their former medical schools. The Israeli Government and the University naturally felt that they were morally bound to assist these men to complete their training, and so a medical school has been opened in what must surely be unique circumstances. As the University still has no access to its own buildings all the teaching will have to take place in the present temporary quarters.

Ex-Service men who have passed their second M.B. examination are being admitted to clinical courses which will be adjusted to their special circumstances and will lead to a degree in medicine. Students who have done most of their preclinical work will be given revision courses, which will of necessity consist mainly of lecture work, and will proceed to a special second M.B. examination. Finally, new students are being accepted for the equivalent of a first M.B. course, which will extend over two years.

Return to Mount Scopus

It is hoped that during the coming months relations with Transjordan may improve sufficiently to enable the University to return to its own home on Mount Scopus, where normal teaching and research could be resumed. The medical school will be quite small, admitting about 50 students a year, and later may accept some dental students also. Buildings still to be erected will cost about £1,000,000, and several years may elapse before they are ready for use. The completed medical school will be well equipped on modern lines. The teachers are of high standing and extremely keen, and there is every reason to hope that the new school will become one of the leading institutions of its kind in the Middle-East.

The present prospects for the medical profession in Israel are not bright. There are more doctors in the country than are really needed. The chief medical insurance organization, the Workers Sick Fund, which employs a good many whole-time doctors to serve the needs of the workers in the chief trade unions, pays its doctors badly and works them hard. Private practice is rapidly dwindling, because all the new immigrants and all the men and women called up for National Service, and their families, are automatically made members of the Workers Sick Fund, and the minimum number of additional new doctors is then engaged by the Fund. There is talk of a National Health Service to be organized by the Israeli Government. Some account of this proposal was given in the *Journal* of May 7 (p. 817). Unfortunately the bargaining position of the doctors is extremely weak, and there is a grave danger that most of the

doctors in Israel may have their standard of living reduced below that of skilled craftsmen, taxi-drivers, or building labourers. It is to be hoped that the Israeli Government and the trade union organizations which so greatly influence government policy will appreciate that in the long run it is wise to maintain the status of medicine as a learned and honourable profession.

CONTROL OF TRYPANOSOMIASIS

INSECTICIDES AND ANTRYCIDE

The relation of the recently discovered "antrycide" to the problem of tsetse-fly disease was the subject of an address by Dr. D. G. Davey, one of the team responsible for the work on this drug, at a joint meeting of the Royal Empire and Royal African Societies on May 25.

On the value of insecticides in general in the control of tsetse-fly disease Dr. Davey expressed some scepticism. Both D.D.T. and gammexane killed the tsetse fly easily and quickly if they were brought into contact with it. Extinction was difficult enough even when small pockets of tsetse country were being treated, but in continuous stretches of bush extending for hundreds of miles it was well-nigh impossible. Work had therefore been directed to the discovery of a drug which could be given to domestic animals to kill any trypanosomes and to protect them from further infection.

The task of fashioning the drug—very much a matter of trial and error—was carried out by a team of biologists, synthetic chemists, and biochemists, assisted by hundreds of mice, with some rats and rabbits. Modern drugs, Dr. Davey pointed out, were "fine tools that only interfere, as it were, with the free life of the organisms that cause disease, rather than cudgels which bludgeon them out of existence."

The properties which a drug for this purpose must possess were: (1) the ability to cure animals infected with the disease, and, moreover, to cure them with a single dose, preferably given under the skin; (2) an action not confined to one species or organism; (3) a certain flexibility allowing a considerable margin of error in its use; and (4) prophylactic powers. He claimed that antrycide possessed these properties in greater measure than any other drug. With the co-operation of the Colonial Office and the Sudan Government, field trials of antrycide had been made in East Africa and the Sudan, and it had been shown that the curative powers of the drug were good, that its action extended not only to trypanosomes commonly found in cattle but also to those in horses and dogs, that it conferred on treated cattle a protection lasting several months, and that it was simple to use. Not sufficient was known about antrycide as yet to state its positive failings. Only further trials would show what contribution to the development of Africa it could make.

Resistant Strains

Dr. Davey went on to indicate some difficulties which he foresaw. These were not confined to antrycide alone. It was possible, for example, that as the use of the drug extended over the enormous territory of Africa strains of trypanosomes would be encountered which would behave differently from those treated already. Again, the misuse or abuse of antrycide might lead to the production of artificially resistant strains. Many of the people who would be employed in the administration of the drug would be lacking in a sense of responsibility, to say the least, and others might be frankly dishonest in measuring doses, and, should this happen, then sooner or later the trypanosomes would become trained to resist even full doses.

A third potential failing was bound up with this possibility of the development of resistant strains. When a drug was given to confer protection on an animal the protection did not last for ever; the drug was slowly eliminated, and eventually a time came when the amount present was insufficient to help to kill trypanosomes, yet this very small concentration of drug might yet be sufficient to influence future behaviour to the drug, so that the trypanosomes would be trained to resist higher concentrations.

At present there seemed to be two main ways of settling a tsetse area. The first was to try to persuade people to enter the area without animals; this was extremely difficult. The other way was to clear the area before the people entered, and this was very expensive. Now a third way would become possible. People might enter virgin tsetse country with their cattle protected by anticyde, and know that their animals would remain fit and healthy for from four to seven months. They could then be re-treated and a further period of protection obtained, and perhaps a third and a fourth, and during this period, covering two years or so, because of the presence of people the game would have receded and the reservoir of infection would have dwindled.

Dr. Davey said that he had been particularly impressed by an experiment done in Kenya. Just over a hundred miles from Nairobi, lying alongside the Mombasa-Nairobi road, was a heavily infested tsetse area. In it was a map point—it could hardly be called a place—called Kiboko. Cattle were put into Kiboko last October, some treated and some untreated. The first of the untreated cattle died five weeks after it entered the area; the last was dead within eleven weeks. One or more of the treated cattle started to look ill rather more than four months after their entry into the fly area; many of them still looked fit, and some of them were apparently free of infection after six months amongst the tsetse fly.

ALEXANDER PIGOTT WERNHER MEMORIAL TRUST FUND

In accordance with a scheme approved by the trustees, an allocation of £4,000 per annum has been made for the award of travelling fellowships or grants in furtherance of the objects of the Fund, which are defined as being "the prevention and cure of blindness and deafness in the United Kingdom and British Empire, and in particular research in connexion therewith by financing medical men and students within the Empire to study methods and practices in all countries of the world." These awards will be made primarily for research in ophthalmology and otology for periods of up to a year, but grants may also be given for short-term visits abroad to study new methods of investigation and treatment in these fields. These funds will be administered by the Medical Research Council, and applications should accordingly be addressed to the secretary of the Council, 38, Old Queen Street, Westminster, London, S.W.1.

Reports of Societies

PREGNANCY AND TUBERCULOSIS

A joint meeting of the Newcastle-upon-Tyne Obstetrical and Gynaecological Society and the North of England Tuberculosis Society was held on March 25 in the Medical School, King's College, Newcastle-upon-Tyne.

Professor E. FARQUHAR MURRAY, president of the Obstetrical Society, was in the chair. He said that, while no one would dispute the inadvisability of a tuberculous mother undergoing the strain of lactation, the effect of pregnancy on the tuberculous process and particularly on its ultimate prognosis was still obscure. In many cases where termination had been advised there appeared to be doubt about the activity of the disease, and even when the disease was active doubt remained about whether termination of the pregnancy was really justifiable or not. His considered opinion was that those cases which were going to improve did so, and those doomed from the start went steadily downhill whether pregnant or not and in spite of treatment.

After stressing that young women with tuberculosis should be advised not to marry or to become pregnant for at least a year after a clinical cure of the tuberculosis, he asked what were the criteria of cure. He referred to the teaching that termination should be undertaken before the third month but not after that, and pointed out that this was illogical. Finally he said that a case might be made out for the induction of premature labour and forceps delivery in cases of respiratory embarrassment, particularly in cases with a recently induced artificial pneumothorax.

Analysis of Cases

Dr. ROWLANDS said that in his opinion pregnancy had no serious influence on the course of pulmonary tuberculosis, provided that the patient was treated appropriately both during the pregnancy and after the confinement. In the case of a seriously ill woman who became pregnant, termination of the pregnancy would not prevent a fatal termination of the disease; therefore the pregnancy should be allowed to go to term and the child, invariably quite healthy, should be allowed to survive.

The case records of 67 women who became pregnant while suffering from pulmonary tuberculosis had been examined and the results tabulated.

Total Cases (67)	Condition at time of Confinement	Following Confinement		Present Condition			
		Deterioration	No Deterioration	Disease Quiescent	Disease Still Active	Died	
Sputum positive (32)	Quiescent	16	1	15	15	1	—
	Active	16	12	4	4	7	5
Sputum negative (by direct smear only) (35)	Quiescent	32	4	28	30	2	—
	Active	3	3	—	2	1	—

The histories of the 16 sputum-positive active cases were discussed. They showed that when the disease was advanced and treatment inadequate—usually because of the refusal of the patient to undergo institutional treatment—deterioration took place. This happened with 12 of the patients, and 5 died. Four who had adequate treatment during and following the pregnancy continued to make satisfactory progress and eventually became quiescent. In the case of one woman, who was delivered of an illegitimate child, deterioration and eventual death could be ascribed partly to psychological changes. Another of the deaths did not take place until three years after the confinement; deterioration was not noticed until nearly two years after the baby was born and could not then be ascribed to the effects of pregnancy.

The great majority of the other 51 cases had had treatment of one sort or another before they became pregnant, with control of the disease in most cases. Where the disease was quiescent before pregnancy the risk of breakdown was slight, and if it did take place could be checked comparatively easily by proper rest and treatment. Only in cases of active open tuberculosis was deterioration to be expected, but not more so than could be looked for in a comparable stage of the disease in non-pregnant women.

Controlled Investigations

Dr. WOLLASTON pointed out that radiological examinations at antenatal clinics showed an incidence of tuberculosis no greater than in comparable groups. Out of 379 consecutive female admissions to sanatoria only 24 had been pregnant within the previous twelve months. Breakdown of a quiescent lesion during pregnancy could be expected in 7% to 10% of cases, but follow-up of female patients whose disease was quiescent on discharge from sanatoria revealed a relapse rate of 11.3%. In the active cases most writers considered that deterioration was accelerated by pregnancy, but Cohen's deterioration rate of 30% should be compared with the relapse rate of 34% for all female patients discharged from sanatoria. Steward and Simmond's controlled investigation showed no statistical difference in the deterioration rate between comparable series of pregnant and non-pregnant women, in both quiescent and active series of cases.

He considered that pregnancy and child-bearing played little part in the onset and relapse of pulmonary tuberculosis. The important factors were those governing the management of any case of tuberculosis: early and adequate treatment, environmental and economic factors, and the psychological reaction of the mother. Pregnant women should have access to sanatoria so that the lesion could be kept under control before labour. Collapse therapy should be ever possible and without delay; it would terminate pregnancy. The strains a

and worry, and lack of rest that played so large a part in causing relapse were aggravated by child-rearing, and the difficulties in bringing up a child must be taken into account when the question of termination was considered. No tuberculous patient should bring up a child without help in the home, especially at night, for the early months. The mother of the unwanted child or the mother who was frightened of pregnancy was far more likely to break down than the mother who was anxious to have a child; in the latter type of cases improvement might follow.

In conclusion Dr. Wollaston suggested that termination of pregnancy, because of the effects of pregnancy, was indicated only when there was a spreading toxic lesion uncontrollable by treatment; but he thought termination was often indicated for reasons indirectly connected with the pregnancy.

Bone and Joint Tuberculosis

Mr. KENNETH STANGER said there were four problems to be considered in cases of bone and joint tuberculosis associated with pregnancy: (1) Was there any evidence of pregnancy lowering the general resistance to tuberculosis and predisposing to the appearance of a skeletal lesion? (2) Whether pregnancy during the active phase of such a lesion had any aggravating effect. (3) If pregnancy occurred rapidly after the lesion had been considered quiescent, was there any increased risk of recrudescence, and, if so, what was a safe interval to allow before pregnancy? (4) What were the possible mechanical problems which might arise and affect pregnancy or delivery?

There were many difficulties in the study of this problem. He had had the opportunity of seeing and treating most of the cases from Newcastle, Gateshead, and Northumberland for 10 years, numbering in all over 400 cases, but the number in which the relationship of pregnancy to tuberculosis could be considered was narrowed to 18 cases.

These 18 cases were described. In this small series pregnancy did seem to diminish the resistance of the patient and predispose to an osseous lesion. Pregnancy occurring during the active phase of the disease had an aggravating effect, but with careful management no permanent ill effects had been noted. In those cases of pregnancy occurring within three years of the disease being recorded as quiescent, two had been reactivated and two were unaffected, one being a case of sacro-iliac tuberculosis delivered normally without ill effect. Finally, the mechanical problems which might arise, such as a large psoas abscess or a lumbar kyphosis, seemed to have no ill effects on the course of pregnancy.

In the discussion which followed, the question of the induction of pneumoperitoneum immediately following delivery, in order to ensure that the diaphragm did not descend too rapidly, was also raised. The general view was that this was an inadequate form of therapy and that other methods of ensuring elevation of the diaphragm—for example, phrenic crush—were more certain and therefore preferable.

TUBAL MOLE

At a meeting of the North of England Obstetrical and Gynaecological Society held in the Algernon Firth Pathological Department, Leeds, on May 20 the chair was taken by the president, Mr. S. B. HERD.

Professor ANDREW M. CLAYE described the case of a patient of 28 with fever and left-sided abdominal pain five days after delivery. Conservative treatment was instituted, but three days later, as severe pain with fever was still present, the abdomen was opened and a left tubal mole surrounded by matted gut was found and removed. The diagnosis was confirmed microscopically and the patient made a satisfactory recovery. She had had simultaneous intrauterine and extrauterine pregnancies, but she had not subsequently had a further pregnancy. Professor Claye also mentioned a case of ectopic gestation eight months after sterilization by ligating, crushing, and excising a portion of each tube, after which the stumps were buried in the broad ligament.

Dr. H. DOBERMAN described a case of tuberculous cervicitis. Mr. H. AGAR discussed the spontaneous rupture of the uterus during pregnancy in a primigravida, and Mr. D. W. CURRIE reviewed the treatment of stress incontinence.

Nova et Vetera

A SUCCESSFULLY OPERATED CASE OF MEMBRANOUS OCCLUSION OF THE ANUS IN THE SEVENTEENTH CENTURY

The Justices of Peace in the seventeenth century were not a judicial body only; they acted in many ways like the local government authorities of later times. Among their various functions was the relief of the poor. According to the Poor Law Act, 1601, the parishes had to supply the relief, in cash or in kind, and had to appoint the overseers. The general supervision, however, rested with the Justices of Peace, who had the right to levy rates on the parishes or, when necessary, in bigger areas such as Hundreds.

Among the applications to the Quarter Sessions at Manchester which are preserved in the Lancashire Record Office are a number asking for financial support. Some of the applicants based their claims on medical grounds. We have published two such applications in which it is stated that syphilis had been the cause of the distress (Sharpe France and Fessler, *Brit. J. vener. Dis.*, 1945, 21, 177). Not only are the applications, with their description of illness, interesting from the medical point of view, but they are important in that they give some information about the social background of medicine.

Below is the application* of a man from Chadderton (near Oldham), who, in asking for relief and complaining about the overseers, traces his poverty back to the expenses which he had when one of his children, born with a deformity, had been successfully operated on. It seems that it was a case of membranous occlusion of the anus. Aggravating his plight was the factor that his wife could not feed any of her four babies, and that it was necessary to use a "suckling-box." The decision of the Quarter Sessions is sometimes preserved in a marginal note on the application. Unfortunately in this instance there is not such a note, and we do not know whether the Justices of Peace were impressed by the facts reported in the application and granted help.

Midsummer, 1677.

"To the Right Worshipfull the Justices of peace and Quorum at the quarter sessions at Manchester these

"Humbly sheweth that your poore petitioner John Bexwick of Chaderton being a very poore man having a wife and fowre smalle children and his wife neare down lying and the second childe that wass borne wass without any Ishu at his fundament which put me to great charges for I was forced to sell my clothes and my wifs withall that I could mak any money of which wass the first beginning of my poverty for this strange distemper which my child was afflicted with made mee think there as no help which caused mee with the advice of my neybers to send for the minister to crissen my childe, which when he came he demanded of me the cause why I sent for him the childe being so livly and no syne of death which some neighbour women that were in the house declared the cause and did shoo him the greefe which when he saw he took the pains to write to Docter Potter which when he heard of it he sent his man with all hast possible to Docter Hartly of this towne and they were all three at my pore house that same night and taking advice one with another with my consent they tooke the thing in hand and by the diligent use of means and the blessing of god my child is brought to his naturall use of voyding his excrement and forthemore my wife hath not had anny suck at all for anny childe that shee hath had but been forced to norrish them up with suckling box which hath put me to great unconvenyanc as your Worships very well know, and I have beene at the overseers often times but they height me so that I get nothing but faire speeches for they very well know my nesityty for it is very well know among my neighbours that I have been laborrious and diligent in my place to maintaine my family if possibly I could and my wife being in this condition I must needs have som woman with her till god inable her againe and without some relief I cannot therefore I humbly desire your Worships to tak it in to consideration and grant me some lykly thing to maintaine my wife and small children which otherwise are lykly to perrish and your poore petitioner [sic] will pray for your Worships health and happiness."

R. SHARPE FRANCE, F.S.A., F.R.Hist.S.
A. FESSLER, M.R.C.S., L.R.C.P.

A. M. D. writes: Although Dr. Cookson's main life work was centred in the county of Durham he had many friends north of the Tweed. His association with Edinburgh began in his student days at the University and later was revived when he came as an examiner in pathology and also in forensic medicine to the Royal Colleges, in each of which he was a Fellow. Those who knew him in the early period remember him best as an all-round athlete; he got a triple blue—for hockey, cricket, and athletics—and he played hockey for Scotland. This open-air interest remained with him throughout his life, when these strenuous activities were replaced by an intense enthusiasm for angling and for the study of archaeological remains. He had an acute and inquiring mind, and in the midst of heavy routine duties, of hospital and forensic work, he found time to make many interesting observations, only a few of which he published.

In later years increasing work and responsibilities weighed heavily upon Cookson, and he longed for quiet and leisure to pursue the many problems he had encountered. His retirement in 1948 was prompted by this desire, which he had hoped to fulfil after an extended holiday in Canada, seeing both his sons. To one of his activity retirement was merely an occasion for further work, for which he was beginning to chafe when he was suddenly struck down. Cookson was a blend of great professional acumen and refreshing youthfulness. Even in the midst of heavy professional work he would interpolate some quiet joke. He was a delightful and amusing companion, full of quaint stories and pawky sayings, and he loved to act the part of his characters, to the great entertainment of his listeners. He will be greatly missed by those who knew him and who were privileged to be his friends.

Medico-Legal

DISINFECTANT IN MILK

Three Unusual Deaths

Three premature babies who died in Stobhill Hospital, Glasgow, on March 27 were accidentally fed from a bottle containing a mixture of breast milk and "dettol." A formal verdict in accordance with the medical evidence was returned at the inquiry held before Sheriff Wellwood Johnston on May 12.

A pupil midwife described how on the evening of March 26, after removing a bedpan from one ward, she placed on a corner table a bowl of "dettol" solution, which she intended to act as a deodorant. This was the first occasion on which she had done such a thing while at Stobhill Hospital. At the same time she removed a similar bowl which contained about 1 dr. (3.5 ml.) of expressed breast milk. This she took to the formula room on another floor.

Another pupil midwife collected two bowls containing breast milk from two other wards, the milk being taken from the mothers of premature babies. She collected at the same time from the corner table a similar bowl which was half full of a white solution she assumed to be breast milk. She was wearing a mask and was suffering from a cold.

A third pupil midwife, on the same evening at about 8 p.m., went into the formula room and saw that each of the bowls contained what she believed to be milk. In one of the bowls there was about half a pint (284 ml.) of fluid, but this was not unusual. She filled two bottles from that bowl and also poured some of the contents into two other bottles which had not sufficient breast milk. All four bottles were then placed in a saucepan for sterilizing.

A staff midwife who had previously washed the four bottles had not used any "dettol"; she also wore a mask. The nurse in charge of the nursery ward for premature babies made up the ten-o'clock feeds and the sister then tube-fed four babies. The nurse went on to feed another child who refused to suck. The sister meanwhile was having difficulty with another baby. She noticed that one of the tube-fed premature babies was distressed and coughing. The contents of one of the bottles was then found to have an odour of "dettol." The obstetrical registrar was notified.

Medical Evidence

Dr. John Henderson found that the fluid in the bottles looked like expressed breast milk but tasted and smelt of "dettol." He immediately treated the four babies by gastric lavage, nikethamide, and the administration of oxygen. Three of the babies died in the course of the morning of March 27. The first fatal case was a month-old baby, one of twins, delivered prematurely at the end of the seventh month. Another premature baby girl was aged only nine days. The third male baby was also a small premature child and only four days old.

He agreed that "dettol" was widely used as a disinfectant and that in some hospitals it might be used as a deodorant. Very similar bowls of "dettol" were used in the labour room. Steps had since been taken to prevent a repetition of this accident. A colouring agent had been added to all the supplies of "dettol" in the hospital dispensary. He thought that the mixture the babies were given would be roughly half breast milk and half a "dettol" solution of unknown strength.

Dr. Findlay James Ford said that it would be difficult to distinguish between a "dettol" solution and expressed milk, particularly when masks were worn. "Dettol" was used so constantly in the hospital that everybody became accustomed to it: "After you had been in the hospital for about ten minutes I don't think you would even notice the smell."

Professor Andrew Allison, who had performed the necropsies, presented his report. The first baby weighed 3 lb. 15 oz. (1.78 kg.) and had weighed 3 lb. (1.36 kg.) at birth. Deep lividity of the back and cyanosis of the lips were noted. There was partial atelectasis of both lungs. When the abdomen was opened a smell of "dettol" was observed; the stomach contained a small quantity of greenish grumous fluid. The gastric mucosa showed several small erosions. The appearances were those due to an irritant poison and were consistent with the ingestion of "dettol."

The second child weighed 4 lb. 5 oz. (1.95 kg.) and had weighed 4 lb. 8 oz. (2.04 kg.) at birth. There were the same external appearances. Both lungs showed patchy atelectasis, and again there was the odour of "dettol" when the abdominal cavity was opened. At the cardiac end of the stomach the lining membrane showed several small areas of congestion.

The male infant weighed 5 lb. 2½ oz. (2.34 kg.) at birth. The greater part of the middle lobe and about three-quarters of the lower lobe of the right lung were atelectatic. The left lung showed patches of atelectasis. There was considerable redness at the cardiac end of the stomach.

He agreed that all three were small premature infants. The phrase "irritant substance" might perhaps have been used instead of "irritant poison" in each report. Whisky would have been just as fatal to these children. He was not using the word "poison" within the meaning of the Poisons Act but as something that started a train of circumstances that led to death. Any irritant would readily have been fatal with such children. It was well known that "dettol" was a relatively non-toxic substance, but even so it was not a thing to be administered to newly born or premature children.

Finally Mr. Archibald Robert Jamieson stated that he had analysed a sample received from the hospital. This proved to contain 5% of "dettol," 5 to 7% milk, and the remainder water.

Medical Notes in Parliament

INDUSTRIAL HEALTH SERVICES

On June 1 Mr. ATTLEE made a statement on the relationship between the National Health Service and the various health services provided in industry which made a call on medical man-power. He said that, to secure that the country's limited medical resources were used to the best advantage and with regard to economy, it was essential that these services should be organized in such a way as to ensure there was no duplication or misdirection of effort. He had therefore appointed, to advise the Government on this matter, a committee whose members were drawn from the industrial field and various branches of the medical profession. Judge E. T. Dale had agreed to act as its chairman. He suggested to all branches of industry that development of industrial health services should

ON GUARD in tinea territory

Activity is on the increase in swimming pools, baths and other centres of communal activity where the organisms responsible for mycotic infections find their hosts. Key measures to efficient control of such infection are prompt treatment of the developing case and planned protection among likely contacts . . . and in both roles Mersagel is equally effective. Mersagel contains the powerful fungicide, phenylmercuric acetate, in a special water-soluble jelly base. It acts directly against the infecting fungi and maintains intimate contact with the seat of infection. Colourless and therefore clean to use, Mersagel does not normally irritate the skin and is suitable for the patient's personal application

D.F.P.

DI-ISOPROPYL FLUOROPHOSPHONATE

For the treatment of
Glaucoma, Paralytic Ileus and
Myasthenia Gravis

A potent miotic and inhibitor
of cholinesterase

D.F.P. resembles physostigmine in promoting the accumulation of acetyl choline in the tissues. But the inhibition of cholinesterase by D.F.P. is irreversible and occurs at a much lower concentration. Clinical trials show that D.F.P. gives prolonged control of intraocular tension in glaucoma, and is often effective when other miotics fail. D.F.P. also increases the motility of both large and small intestines in paralytic ileus and may reduce the requirement of neostigmine in myasthenia gravis.

Available as:

D.F.P. EYE-DROPS-BOOTS. 0.1% solution in arachis oil. Bottles of 10 ml.

INJECTION OF D.F.P.-BOOTS. Sterile 0.1% solution in arachis oil. Box of 6 x 2 ml. ampoules.

Literature and further information on request to Medical Dept.

BOOTS PURE DRUG COMPANY LIMITED

VASANO

for the prevention and treatment of

'Vasano' consists of
a mixture of hyoscine, hyoscyamine
and camphoric acid in balanced combination which affords
optimal central and peripheral action. Hyoscine, acknowledged
as one of the most effective single agents for the prevention
of travel sickness, exerts a sedative influence on the higher
centres and is a parasympathetic depressant, while
hyoscyamine acts peripherally upon the vagus.

VASANO

is a proven remedy for all forms of travel
sickness, by land, sea or air, and is also widely prescribed for the
treatment of Meniere's Disease.

Painless INTRAMUSCULAR INJECTIONS

e.g. of PENICILLIN, LIVER EXTRACTS,
ARSEN-BENZOLS, BISMUTH, etc.

Many substances create some pain on intramuscular
injection. Novutox injected at the same time will
prevent this pain.

Most substances are compatible with Novutox,
which is also non-destructible to penicillin during
the time that the latter is undergoing absorption.

Mixtures with Novutox should be made
immediately before use ONLY.

NOVUTOX

Self-Sterilising
Local Anaesthetic

Each c.c. of Novutox 2% contains 0.82 gm. ethocaine hcl.,
0.00002 gm. epinephrine and 0.00002 gm. capryl hydro-
cupreinotoxin hcl. Other strengths of Novutox contain these
elements (with or without epinephrine) in varying proportions.

PHARMACEUTICAL MANUFACTURING CO. LTD.
THE LABORATORIES, CHELTENHAM, GLOS.

as far as possible be postponed until the committee's recommendations were available. He hoped that the committee would not take very long to survey the field.

Colonel STODDART-SCOTT asked whether Mr Attlee would extend the inquiry to include the medical service of the Ministry of Pensions and of the Ministry of Education.

Mr ATTLEE said that would delay a decision which was needed. He agreed that the industrial health services should be preserved. What was needed was to prevent overlapping.

The members of the committee are Judge E T Dale (chairman), Mr. John T. Byrne, Electrical Trades Union, Dr T A Lloyd Davies, Chief Medical Officer, Boots Pure Drug Co., Mr R R Hyde, Director, Industrial Welfare Society, Dr Walter Jope, Mr K I Julian, Chairman, South east Metropolitan Hospital Board, Dame Anne Loughlin, former Chairman, TUC, Mr J H Pheazey, Standard Telephones, Ltd, Dr L Roberts, Medical Officer of Health, Sheffield, Dr A T Rogers, and Sir Geoffrey Vickers, National Coal Board. The joint secretaries of the committee are Mr F W Beek, Ministry of Health, and Mr C H Sisson, Ministry of Labour and National Service.

Policy on Sight Testing

On June 2 Mr BEVAN stated that sight testing and the supply of spectacles should, as resources allowed, be carried out in hospitals and clinics provided as part of the hospital and specialist service in charge of ophthalmologists, with opticians playing in them their proper professional part. Government policy was unchanged in this regard.

Port Health Regulations

Answering Mr BOYD CARPENTER on May 26, Mr BEVAN said he had no power to prevent persons from landing because of infectious disease. The Port Health Regulations, 1933 and 1945, prescribed separately the conditions that, in general conformity with the relevant International Sanitary Convention, could be imposed against plague, cholera, yellow fever, typhus fever, and smallpox. Normally the greatest risk to this country was presented by smallpox. If a ship arrived that had, or had recently had, a case of smallpox on board, any person suffering from the disease was disembarked and isolated. Any person exposed to infection on board, unless in the opinion of the Port Medical Officer that person was sufficiently protected by recent vaccination or by a previous attack of smallpox, could be (a) offered vaccination and placed under surveillance for 14 days, or (b) placed under surveillance for 14 days without vaccination, or (c) offered vaccination and isolated until the result of the vaccination is known, and thereafter kept under surveillance for 14 days from the arrival of the ship, or (d) isolated for 14 days after the arrival of the ship.

Requirements (c) and (d) could not be imposed unless the Port Medical Officer considered that there was exceptionally serious risk of the introduction of smallpox into the country. Mr Bevan explained that "surveillance" was defined in the International Sanitary Convention to mean that the persons were not isolated but that the health authorities of the places to which they were going were notified of their coming. Port Health Regulations imposed on such persons obligations designed to secure that they could be effectively supervised. He added that he was considering whether any further powers were needed to check the introduction of infectious diseases from overseas.

Chronic Sick in Mental Hospitals

On May 26 Mr. YATES spoke of the inadequacy of existing facilities for the care of the chronic and aged sick in the city of Birmingham, and asked what steps Mr Bevan proposed to take to improve these facilities.

Mr BEVAN said, in reply, that the Regional Board had two groups of experts investigating the problem, and would take further action in the light of their reports. Meanwhile, unused beds were being brought into use wherever possible and arrangements made with the local health authority for home nursing.

Mr YATES said that in the past year more than 90 aged persons, chronically sick, had been admitted to mental hospitals, of whom about 17 had died within a month of admission.

Mr BEVAN said it should not be assumed that they died because they went to hospital. They were not in the mental hospital as such, but occupied the same physical accommodation as other people. During the war a great deal of the E.M.S. had been housed in separate parts of mental hospitals. He could not accept the statement that old people were certified as mental cases in order to be taken into hospital. That was

a gross and offensive charge against the doctors concerned. As for the statement that a proportion of the patients had died from heart failure, people had died from that cause for millions of years. Members should be ashamed of saying that the doctors and magistrates concerned with certification were certifying old people who were not "mental".

Asked later by Mr YATES to what extent the Birmingham mental hospitals were understaffed, Mr. BEVAN said that at Winslow Green Hospital the deficiency of female nursing staff was 28% and of male 27%. At Rubery Hill the deficiency was female staff 50%, male staff nil. Persistent efforts were being made to recruit staff through the Ministry of Labour and by local recruiting campaigns and advertisement.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

In Congregation on May 28 the following medical degrees were conferred

M.D.—E B Davies O B Appleyard, F S Carter
M.B., B.Ch.—S G A. Forsyth (by proxy)

The Services

The Emperor of Ethiopia has conferred the Haile Selassie I Military Medal with one Palm upon Lieutenant-Colonel (Temporary) C B Drew, MBE, R.A.M.C., in recognition of distinguished services in the cause of the Allies.

The Socialist Medical Association has proposed a syllabus for a two year basic training in nursing. The emphasis is on practical training rather than on teaching the nurse theoretical knowledge which she may never need to use. Dr Hugh Gainsborough points out in a foreword that "a nurse does not need to memorize the names of pancreatic enzymes in order to care for a patient suffering from carcinoma of the pancreas." He also advocates postgraduate education for ward sisters.

No. 20

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 21.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland. Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Deaths from measles and scarlet fever for England and Wales, London (administrative county), will no longer be published.

‡ Includes primary fever for England and Wales, London (administrative county), and Northern Ireland.

§ The number of deaths from poliomyelitis and polio-encephalitis for England and Wales, London (administrative county), are combined.

|| Includes puerperal fever for England and Wales, Eire, and Northern Ireland.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales there was an increase in the notifications of scarlet fever 115, measles 115, and acute pneumonia 35. There was a decrease in the incidence of whooping-cough 82 and dysentery 22.

A small rise in the incidence of scarlet fever occurred in most areas, and there were no large changes in local trends. The increased incidence of measles was mainly contributed by the south midland counties; the largest rises were Middlesex 101 and Nottinghamshire 80, and the largest decrease was in Yorkshire West Riding 51.

There were decreases in the notifications of whooping-cough in Warwickshire 48 and Yorkshire West Riding 43.

There was a decrease of 6 in the notifications of diphtheria in London and an increase of 5 in Lancashire and in Durham.

Of the 55 cases of dysentery 23 were notified in Lancashire (Oldham C.B. 15 and Liverpool C.B. 6). Three cases of smallpox were notified from Cornwall, Liskeard R.D.

In Scotland there was an increase in the notifications of measles 36 and of acute primary pneumonia 32. There were decreases in the notifications of scarlet fever 40 and dysentery 16. In Glasgow a rise of 21 in the notifications of acute primary pneumonia was recorded, and in this city 14 of the 19 cases of dysentery were notified.

In Eire notifications of whooping-cough increased by 30, while a decline was reported in the incidence of primary pneumonia 12 and measles 19.

In Northern Ireland there were decreases in the notifications of measles 19 and whooping-cough 11.

Week Ending May 28

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,233, whooping-cough 2,611, diphtheria 100, measles 9,583, acute pneumonia 485, cerebrospinal fever 39, acute poliomyelitis 19, dysentery 85, paratyphoid 8, and typhoid 4.

Medical News

Locum Register for Tuberculosis Work

The National Association for the Prevention of Tuberculosis has set up a Locum Register where names will be kept of doctors looking for temporary positions in clinics and sanatoria, together with a brief note of their medical qualifications. Those who want locum work of this kind are asked to write to the N.A.P.T. Locum Register, Tavistock House North, London, W.C.1, giving the necessary details and, if possible, a telephone number.

Waiting-list for Mental Defectives

The North-East Metropolitan Regional Hospital Board reports that there is a serious shortage of hospital accommodation for mentally defective patients. In that region there is a waiting-list of over 400; at the present rate of admission to the existing accommodation those at the bottom of the list are unlikely to be admitted in less than 8 to 10 years. The mental health committee of the board has recommended the board to obtain permission from the Minister of Health to start erecting temporary accommodation immediately for at least 200 patients. There is also a long-term project for building more permanent accommodation.

Special Diets for Invalids

Doctors who have not received a copy of the Ministry of Food's memorandum Med. 2 (Revised 1948), which describes the arrangements for granting extra rations and priority allowances of food to invalids and people needing special diets, may obtain it from the local food office.

Pharmaceutical Society

Mr. H. Clement Shaw, of T. C. Cornwell Ltd., has been re-elected president of the Pharmaceutical Society of Great Britain for twelve months. Mr. J. F. McNeal and Mr. W. Spencer Howells have been re-elected vice-president and treasurer respectively.

Croydon Executive Council Chairman

Dr. S. A. Forbes has been appointed chairman of the Croydon Executive Council, and has therefore resigned his chairmanship of the Croydon Local Medical Committee. The new chairman of the committee is Dr. R. N. Deane, and Dr. H. H. A. Elder is vice-chairman.

Public Health Salaries

The salary offered for the post of assistant medical officer advertised by Merthyr Tydfil in this issue of the *Journal* conforms to the scale recommended by the B.M.A. It is the first to appear since the ban was imposed on advertisements not in conformity with that scale, and which continues until the local authorities have indicated that they will enter into negotiations on new scales.

Hospital Cots

Referring to the case of a baby that died from a dislocated neck after squeezing his head through the bars of a hospital cot, the Minister of Health has asked hospital boards and committees to take steps to prevent a similar occurrence in their hospitals, such as lashing two-inch twine netting to the bars of cots. Meanwhile new cots should not be purchased unless the maximum space between bars is $3\frac{1}{2}$ ins. and the minimum space 3 ins.

Visited Sweden

Professor Alan Moncrieff, Director of the Institute of Child Health (University of London), has recently visited Sweden at the invitation of the medical faculties to lecture in Stockholm, Uppsala, and Lund.

For Cancer Research

The British Empire Cancer Campaign has granted £1,865 to Oxford University to be used for cancer research in the Dyson Perrins Laboratory.

British Medical Graduates in the U.S.A.

The American Alumni of British Medical Schools, formed in 1940, has recently been incorporated under the laws of the State of New York. Its functions are to serve the interests of graduates of British schools of medicine. Doctors who are graduates of schools within the British Commonwealth of Nations, including the Irish Free State, and who wish to join this organization should communicate with Dr. Theodore Meltzer, secretary, 123 East 37th Street, New York City, 16.

Rest for Nurses

The following "rest-break houses" for nurses and midwives have been opened under the management of the Council for the Provision of Rest-break Houses for Nurses and Midwives (106, St. Clement's House, London, E.C.4): Barton House Hotel, Barton, New Milton, Hants (accommodation for 48); Drygrange Hotel, Melrose, Roxburgh, Scotland (accommodation for 28, to be increased to 55); Peveril House, Buxton, Derbyshire (accommodation for 27). Applications for accommodation should be made direct to the wardens of the houses. These houses are intended to provide a rest for tired nurses and midwives whose health might break down; they are not for convalescents or holiday-makers. Sick leave should be granted with the appropriate pay when a nurse or midwife stays at a rest-break house, but those using the houses will not normally be eligible for sickness benefit under the National Insurance scheme.

R.S.M. Photographic Unit

The photographic unit of the Royal Society of Medicine was founded in December, 1945, with the aid of a generous grant from the Rockefeller Foundation. The short-term policy of the unit was to assist in the rehabilitation of medical libraries which had been damaged owing to the war. It has supplied, with the agreement of the publishers concerned, whole volumes or issues of out-of-print medical periodicals on microfilm. The unit can now serve other organizations, as well as Fellows of the Society, on a basis of non-profit-making payment. It can do photographic work other than microfilming, such as the making of a film strip, lantern slides of all sizes, direct positive prints from x-ray negatives whether in the form of slides, prints, or microfilm, enlargements of clinical photographs, and the making of colour transparencies on 35-mm. film. In addition clinical photography of patients and specimens can be undertaken.

Shortage of Doctors in U.S. Forces

The United States armed Forces estimate that by July 31, 1949, they will face a shortage of 1,600 doctors and 1,160 dentists. By December, 1949, the deficiency is expected to be 2,200 doctors and 1,400 dentists. The Secretary of Defence, Mr. James Forrestal, has therefore opened a national campaign to obtain volunteers from among the younger doctors and dentists who were educated at Government expense or who were deferred from military service because of their status as medical or dental students. Of approximately 18,000 doctors who were given Government grants while students, only some 10,000 served with the Forces; several thousand more men were deferred in order to continue their education. Volunteers will be expected to serve for at least twelve months, and will receive \$100 per month in addition to prescribed pay and allowances. As far as possible volunteers will be employed in posts for which their abilities suit them.

Ambulance Radio

The first ambulances in the United Kingdom to be fitted with radio for emergency calls and general control are being used in Guernsey. Radio apparatus has been installed in five St. John ambulances on the island, and radio calls to ambulances near the spot enable seriously ill patients to be rushed to hospital or to a doctor in a matter of minutes. Each of the five ambulances is able to keep in touch with the others or with headquarters, and over 4,000 calls have been dealt with in the twelve months that the ambulances have been operating.

National League of Hospital Friends

Since the Health Service started, local Leagues of Hospital Friends or similar voluntary organizations bearing other names have been formed with the purpose of maintaining personal interest in hospitals and their patients. The organizations have now formed the National League of Hospital Friends to provide a centre through which they can exchange information and advice. Individuals as well as local leagues may join the National League. Lord Luke is president, Lady Monckton honorary treasurer, Mr. J. P. Wetenhall chairman, and Mr. R. F. Millard acting honorary secretary. A survey recently made by the British Hospitals Association shows that some 560 hospitals have the interest and support of 175 leagues.

Milk from Hospital Farms

Though the Milk and Dairies Regulations, 1926-43, do not apply to hospital dairy farms, the Minister of Health considers that the hygienic requirements prescribed in them should be complied with where possible. At present the State Veterinary Service will continue to carry out tuberculin testing and clinical examination of herds at hospital farms which up to July 5, 1948, were licensed for the production of tuberculin-tested milk, as well as the clinical examination of herds which were licensed for the production of accredited milk and of any herds not so licensed. Local authorities have been asked to take at least twelve samples of milk a year from each of the herds at hospital dairy farms for examination by the methylene-blue test. Boards of governors and hospital management committees should arrange for at least one sample to be taken every three months for biological examination for organisms of tuberculosis and for examinations for *Brucella abortus*. The services of the Ministry's milk inspectors are available on request.

Central Council for Health Education

At its quarterly meeting on April 28 the Central Council for Health Education approved a plan for holding a conference on the objects and methods of health education on Nov. 8 and 9. Dr. Robert Sutherland will spend September and October in the U.S.A. studying the methods of health education there under the auspices of the Rockefeller Foundation.

London Irish Golf

The winners of the competitions held by the London Irish Medical Golfing Society at Sunningdale on May 26 were: Embryo Cup, Dr. J. T. McCarthy; Nelligan Cup, Dr. W. Houston.

Wills

Dr. George James Irvine Linklater, formerly chief executive school medical officer for Edinburgh, left £1,367. Dr. Samuel Robert Hunter, of Dunmurry, Co. Antrim, left £35,896. Dr. Francis Henry Swindon Curd, who was responsible for much of the early work on paludrine and atnycide, left £709. Dr. Donald Hugh Cameron, of Sheffield, left £5,724. Dr. Norman John Boulton, of Kintbury, Berks, left £17,231.

COMING EVENTS

Birmingham Consultants' Meeting Cancelled

The general meeting of consultants in the Birmingham Region, announced to take place on June 11, has been cancelled.

Conference on Maternity and Child Welfare

The National Association for Maternity and Child Welfare will hold its annual conference at Friends House, Euston Road, London, N.W., on June 22, 23, and 24. The general theme of the conference will be "The Effects of Recent Social Legislation on Mothers and Children," which will be discussed in relation to health, education, and welfare. The Minister of Health will deliver an address at the close of the conference, which will be opened by Dr. Charles Hill. Other speakers will include Dr. E. K. Macdonald, Dr. Nora Wattie, Dr. Barbara Bailey, Mr. G. H. Sylvester, Mr. Douglas Houghton, M.P., and Dr. May Baird. Visitors will be welcome either to the whole conference or to single sessions. Full particulars can be obtained from the secretary of the association, 5, Tavistock Place, London, W.C.1.

Golf Competition

The annual competition for the North Manchester Medical Golf Cup will be held at Manchester Golf Club, Hopwood, near Middleton, on June 29. The cup is awarded to the player returning the best net score over eighteen holes. The entrance fee is 7s. 6d. Inquiries should be addressed to Dr. J. A. Strachan, 566, Broadway, Chadderton, Lancs, on or before June 25.

Addison Lecture

The third Addison Lecture will be delivered in the physiology theatre, Guy's Hospital Medical School, London Bridge, S.E., on Thursday, June 23, at 5 p.m., by Sir Henry Dale, O.M., F.R.S., on "Thomas Addison—Pioneer of Endocrinology." The chair will be taken by Sir Herbert Lightfoot Eason, and applications for tickets should be made to the Dean, Guy's Hospital Medical School, London, S.E.1, by Thursday, June 16.

International Congress of Biochemistry

The 1st International Congress of Biochemistry will be held at Cambridge on Aug. 19-25. Information may be obtained from the Honorary Organizer, Lieut-Col. F. J. Griffin, 56, Victoria Street, London, S.W.1. The Congress is in twelve sections: (1) Animal Nutrition and General Metabolism: Chairman, Sir Jack Drummond, F.R.S.; Secretary, Dr. L. J. Harris, Sc.D. (2) Microbiological Chemistry: Chairman, Dr. M. Stephenson, Sc.D., F.R.S.; Secretary, Dr. E. F. Gale, Sc.D. (3) Enzymes and Tissue Metabolism: Chairman, Professor R. A. Peters, F.R.S.; Secretary, Dr. D. M. Needham, Ph.D., F.R.S. (4) Proteins: Chairman, Dr. K. Bailey, Ph.D.; Secretary, Dr. R. R. Porter, Ph.D. (5) Clinical Biochemistry: Chairman, Professor E. J. King; Secretary, Dr. E. N. Allott. (6) Structure and Synthesis of Biologically Important Substances: Chairman, Professor A. R. Todd, F.R.S.; Secretary, Dr. B. Lythgoe, Ph.D. (7) Cytochemistry: Chairman, Professor J. N. Davidson; Secretary, Dr. Charity Weymouth, Ph.D. (8) Biological Pigments: Oxygen Carriers and Oxidizing Catalysts: Chairman, Professor D. Keilin, F.R.S.; Secretary, Dr. E. F. Hartree, Ph.D. (9) Hormones and Steroids: Chairman, Professor F. G. Young; Secretary, Dr. F. L. Warren, Ph.D. (10) Chemotherapy and Immunochemistry: Chairman, Sir Charles Harington, F.R.S.; Secretary, Dr. T. S. Work, Ph.D. (11) Plant Biochemistry: Chairman, Dr. C. S. Hanes, Ph.D., F.R.S.; Secretary, Professor T. A. Bennet-Clark. (12) Industrial Fermentations: Chairman, Mr. H. J. Bunker, M.A.; Secretary, Dr. P. W. Brian, Ph.D.

SOCIETIES AND LECTURES**Monday**

EDINBURGH UNIVERSITY.—At Physiology Lecture Theatre, University New Buildings, Teviot Place, Edinburgh, June 13, 5 p.m., "*The Microscope: Origin and Evolution*," by Dr. Douglas Guthrie.

LONDON: UNIVERSITY COLLEGE.—At Physiology Theatre, Gower Street, W.C., June 13, 4.45 p.m., "*Selective Toxicity with Special Reference to Chemotherapy*," by Professor Adrien Albert.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, Cavendish Square, W.—June 13, 8.30 p.m., Films: "*The History of the Cinema Film in Medicine*"; "*Angina Pectoris*"; and "*Removal of Foreign Bodies from the Eye*."

Tuesday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., June 14, (1) 11 a.m., "*Gonorrhoea in the Female*," by Dr. W. N. Mascall; (2) 5 p.m., "*New Growths of the Bladder (Benign)*," by Mr. C. H. Mills.

LONDON: UNIVERSITY COLLEGE.—At Physiology Theatre, Gower Street, W.C., June 14, 5.15 p.m., "*Muscular Contraction*," by Professor A. V. Hill.

Wednesday

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., June 15, (1) 11 a.m., "*Vulvo-vaginitis in Children*," by Dr. W. N. Mascall; (2) 5 p.m., "*New Growths of the Bladder (Malignant)*," by Mr. C. H. Mills.

NATIONAL HEART HOSPITAL: ROYAL SOCIETY OF MEDICINE.—At 1, Wimpole Street, W., June 15, 5 p.m., "*Withering*," St. Cyres Lecture by Professor K. D. Wilkinson.

PHYSICAL SOCIETY: COLOUR GROUP.—At Institute of Ophthalmology, Judd Street, London, W.C., June 15, 4 p.m., 46th Science Meeting. "*The History of Artists' Pigments*," by Dr. H. J. Plenderleith. Followed by discussion.

WEST LONDON HOSPITAL MEDICAL SCHOOL.—At Medical Society of London, 11, Chandos Street, W., June 15, 8.30 p.m., "*Surgical Treatment of Congenital Pulmonary Stenosis*," Second Alexander Simpson-Smith Memorial Lecture by Mr. R. C. Brock.

WEST LONDON INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School, Paddington, W.—June 15, 5.30 p.m., "*Treatment of Bacterial Arthritis*," by Dr. Leon Unger (Chicago).

Thursday

DREADNOUGHT SEAMEN'S HOSPITAL, Greenwich, London, S.E.—June 16, 3 p.m., demonstration by Mr. D. M. Cooper.

HARVEIAN SOCIETY OF LONDON.—At Royal College of Surgeons of England, Lincoln's Inn Fields, London, W.C., June 16, 7.15 for 7.30 p.m., Buckston Browne-Gray Hill Annual Dinner.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, Endell Street, London, W.C., June 16, (1) 11 a.m., "*Systemic Gonorrhoea*," by Dr. A. H. Harkness; (2) 5 p.m., "*Congenital Defects of the Testicle and Epididymis*," by Mr. Harland Rees.

LONDON: UNIVERSITY COLLEGE.—At Physiology Theatre, Gower Street, W.C., June 16, 4.45 p.m., "*Some Aspects of Nitrogen Metabolism in the Mammal*," by Dr. J. S. Bach.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 26, Portland Place, London, W.—June 16, 7.30 p.m., Annual general meeting, induction of new president; Professor H. E. Shortt, and presentation of Chalmers Gold Medal for 1949; film, "*Chagas' Disease*," shown by Dr. R. V. Talice (Montevideo).

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, London, S.W.—June 16, 4.30 p.m., "*Neurology*," lecture-demonstration by Dr. A. Feiling.

Friday

BIOCHEMICAL SOCIETY.—At Department of Chemistry, The University, Nottingham, June 17, 2 p.m., 277th meeting.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Central Middlesex Hospital, Park Royal London, N.W., June 17, 3 p.m.

Saturday

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Queen Mary's Hospital, Carshalton, Surrey, June 18, 3 p.m., clinical meeting.

APPOINTMENTS

LODER, R. E., M.B., B.Ch., D.A., Specialist Anaesthetist, Peterborough Area, East Anglian Regional Hospital Board.

SALFIELD, DEREK J., M.D., Assistant Psychiatrist, Crichton Royal Mental Hospital, Dumfries.

SCHROEDER, BERNARD, M.B., Ch.B., D.P.H., Assistant County Medical Officer, North Riding of Yorkshire County Council, Medical Officer of Health, Whitby Urban District and Whitby Rural District.

BIRTHS, MARRIAGES, AND DEATHS**BIRTHS**

Allen.—On May 23, 1949, in London, to Judy (née Collins), wife of Richard A. Allen, M.B., B.S., a son.

Jackson.—On June 5, 1949, at Oxford, to Barbara (née Bonsey), wife of Dr. C. R. S. Jackson, a son.

Keppich.—On May 31, 1949, at Bristol, to Enid, wife of Dr. Peter H. Keppich, a son—Mark Arnold.

Lauckner.—On May 23, 1949, at East London, South Africa, to Dr. Helena (née Taylor), wife of Dr. J. R. Lauckner, Lovedale, C.P., South Africa, a son.

Marien.—On May 28, 1949, at Thorpe Coombe Hospital, to Joan, wife of Dr. E. A. W. Marien, a daughter—Ange's Isabel.

Messer.—On May 27, 1949, to Olive (née Dawson), wife of Basil Messer, M.B., B.S., 1, Undercliffe Street, Bradford, a son.

Rayner.—On May 28, 1949, at Queen Elizabeth Hospital, Birmingham, to Dr. Mary M. Rayner (née Dale) and Captain C. Stephen Rayner, Royal Signals, a daughter—Juliet Mary, a sister for Christopher.

Roberts.—On May 25, 1949, at St. Chad's Hospital, Birmingham, to Margaret (née Holloway), wife of Dr. Keith D. Roberts, a daughter—Diane Marguerite.

Thornley.—On June 1, 1949, at Manchester, to the wife of Mr. Roland Thornley, F.R.C.S.Ed., a son.

Whitehouse.—On May 26, 1949, at Queen Mary's Maternity Home, Hampstead, to Joan L. (née Tully), wife of Dr. Dennis Whitehouse, a son—Peter John.

DEATHS

Fletcher.—On May 23, 1949, at "Beechwood," Workington, Isaac Fletcher, M.B., C.M., D.P.H., J.P., in his 86th year.

Fox.—On June 1, 1949, Campbell Tibury Fox, M.R.C.S., L.R.C.P., of "St. Margaret's," The Avenue, Littlestone, Kent, and late of Ashford, Kent, aged 77.

Frost.—On June 1, 1949, at 3, Parkside Road, Reading, Augustine Thomas Frost, O.B.E., M.B., B.Ch., Lieutenant-Colonel, R.A.M.C. (ret.), aged 71.

Grayling.—On May 31, 1949, Arthur Grayling, M.B., late of Forest Hill, London, S.E., aged 91 years.

Henderson.—On June 1, 1949, John Henderson, M.D., F.R.F.P.S., Professor of Medicine in St. Mungo's College, Glasgow, from 1913 to 1947, of 6, Newton Place, Glasgow.

McAllen.—On May 31, 1949, at "The Thatched Cottage," Llanwrn, Monmouthshire, Thomas John McAllen, M.B., B.Ch., of Pontypool.

MacLeod.—On April 30, 1949, at Sydney, New South Wales, Charles Gordon MacLeod, M.D., F.R.A.C.S.

Rosenbloom.—Suddenly, on June 1, 1949, at Western Infirmary, Glasgow, Alfred Rosenbloom, M.B., Ch.B., D.T.M., Colonel, I.M.S. (ret.), aged 46, beloved husband of Leah Rosenbloom, M.B., Ch.B.

Shannon.—On May 28, 1949, at 253, Green Lanes, Palmer's Green, London, N., Frederick Shannon, M.B., Ch.B., aged 64.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Bee-stings

Q.—What are the current views on bee-stings? What is known about the nature of the venom; single and multiple stings; anaphylaxis or hypersensitivity, and any other possible complications? What is the best treatment?

A.—The poison-gland system of a bee consists of a small alkaline and a larger acid gland. Bee venom is a complex substance which, it is suggested, contains histamine and a combination of lecithin with basic radicals somewhat resembling apotoxins and cantharidin. It does not contain formic acid. A single sting as a rule causes only a slight local reaction, but if it occurs on the tongue or fauces it may cause oedema of the glottis. Some people, usually as the result of repeated stinging, become allergic to the venom, and this will result in a large painful swelling at the site of the sting with or without a generalized urticaria; in highly sensitive subjects generalized angioneurotic oedema, severe dyspnoea, coma, and death may occur. Death may also occur in non-sensitized subjects from extensive multiple stinging. The sting should be gently removed. Local therapy consists in the application of alkali soap, weak ammonia, sodium bicarbonate solution, methylene blue, alcohol, calamine, or an antihistamine or analgesic ointment. For the milder urticarial reactions an antihistamine drug or ephedrine, or a combination of the two, should be given. For the severe allergic reactions, and for the collapse due to multiple stinging, 5 to 10 minims (0.3 to 0.6 ml.) of adrenaline should be injected and repeated as necessary.

Oestrogens at the Menopause

Q.—Will hormone therapy preserve the secondary sexual characteristics of women at and after the menopause and prevent loss of youthful form, atrophy of the breasts, etc.? Are there any dangers (for example, of carcinogenesis) in prolonged administration of sex hormones?

A.—Oestrogens preserve secondary sex characters to a limited extent in women. They prevent atrophy of the breasts and of the tissues of the genital tract, and in some women at least they increase libido, which tends to wane with advancing years. Their effect on the texture of skin and hair and on bodily figure is, however, less definite, and they do not significantly modify the general process of ageing. The danger of prolonged administration of oestrogens is that they stimulate the uterus to undergo hyperplasia and cause irregular and heavy uterine haemorrhage; they may also stimulate the epithelium of the breasts to unnatural activity. Although oestrogens have been shown to be carcinogenic under certain circumstances in animals, they have never been proved to cause cancer in the human being, and the risk of this was probably exaggerated in the past. They are nevertheless powerful stimulants of the epithelium of the female genital tract, and their prolonged administration might prove an activating factor in the presence of a precancerous lesion or of an inherent susceptibility to malignant disease.

Loss of Ultra-violet Transparency

Q.—Can you provide me with any data concerning the rate of loss of transparency to ultra-violet rays in the quartz of a mercury arc lamp?

A.—The conversion of quartz into its isomers tridymite and cristobalite, which are opaque to ultra-violet irradiation, starts as soon as the burner is put into use. This deterioration occurs most rapidly during the first 500 hours of use, and then takes place more slowly. In the older models after 1,000 hours of

use the intensity of radiation would be about one-half of the original, but in the latest electronic-discharge types only about 20% of the irradiation would be lost in this time. Most burners are fitted with a rheostat by which the intensity of the arc can be increased as the burner grows old, thus maintaining its output. The questioner is referred to Morris's *Medical Electricity* (Churchill, 1946, p. 262) and Kovacs's *Electrotherapy and Light Therapy* (Lea and Febiger, Philadelphia, 1945, p. 352).

Salt Intake and Peptic Ulcer

Q.—Has any research been done on the excessive intake of sodium chloride as a factor in the causation of peptic ulcer? I recently came across four cases of this complaint in which the patients were said to have an undue partiality for salt.

A.—From time to time work has been done on the possible relationship between salt intake and peptic ulcer. Apart from the irritant effect of large doses of salt frequently administered—a factor which seldom arises—the conclusion is that sodium chloride plays no part in the aetiology of peptic ulcer.

Extrasystoles

Q.—Are attacks of extrasystoles always due to sympathetic overaction? I have in mind a man of 42 who suffers from attacks of continued extrasystoles, sometimes passing on to auricular fibrillation. There is no history of rheumatism or venereal disease, and the heart is normal between attacks. These occur about twice weekly and last from two to three hours; they are induced by changes of temperature and also by pain, and are aggravated by cigarette-smoking.

A.—The description given is typical of frequent prolonged bouts of extrasystoles in a person with an otherwise normal cardiovascular system. In some such cases the only means of differentiating these attacks from auricular fibrillation is by an electrocardiogram taken during the phase of irregularity. These bouts are usually accentuated by infection, tobacco-smoking, fatigue, pain, etc. It is not necessarily due to overaction of the sympathetic nervous system, but is a functional condition of the myocardium, and, indeed, attacks in some people may be induced by overaction of the vagus. The prognosis is good and such patients may live to a ripe old age.

The following treatment may be tried in varying combinations: quinine 3 gr. (0.2 g.) three times a day, alone or combined with strychnine; potassium salts, such as potassium acetate 30 to 60 gr. (2 to 4 g.) four times a day, and potassium bromide 10 gr. (0.65 g.) three times a day; phenobarbitone $\frac{1}{2}$ gr. (32 mg.) three times a day. The patient should be reassured and told that the attacks are of no importance and that they may be ignored. If, however, attacks of this kind have been proved by electrocardiography to be due to auricular fibrillation the condition will probably become established unless preventable by quinine, and the outlook is correspondingly more serious. In this case digitalis (which may increase the incidence of extrasystoles) will have to be used for persistent fibrillation.

Precipitating or Delaying Menstruation

Q.—Can anything be done with safety to (a) precipitate, or (b) delay the onset of, a menstrual period? A woman who is to be married on June 12 had her last period on May 19; her cycle is irregular, with intervals of about three weeks.

A.—Injection of neostigmine, 1 mg. daily on three successive days, sometimes precipitates the onset of a period which is overdue, but it is not likely to bring one on prematurely. In the case in question the patient is already in the luteal phase of the cycle, so that the best hope of deferring menstruation is to give daily intramuscular injections of 10 mg. of progesterone, starting not less than three days before the expected onset of the next period—that is, about June 3. The injections will have to be continued so long as postponement of menstruation is desired, and the flow can be expected within 48 hours of suspension of treatment. Oral therapy with ethisterone is not usually powerful enough to defer a period, and, since continuation of injections is likely to be impracticable, there is much to be said for leaving well alone. This is particularly true in this case, because (a) if the patient's present cycle is a three-weekly one

the next period should begin about June 6 and should be finished, or nearly finished, by the time of the wedding; (b) the irregularity of menstruation makes it difficult to time any treatment designed to change the time of onset; (c) the excitement of marriage and preparation for it may well precipitate or postpone menstruation. Even if the dates of marriage and menstruation clash, it should be no great tragedy. Deferment of coitus for two or three days, when the initial emotional excitement of marriage has passed, may favour rather than hinder the early establishment of happy sexual relations.

Resistant Skin Condition

Q.—*Could you suggest diagnosis and treatment for an atrophic condition of the skin of the hands in a man aged 38? He is inclined to be over-conscientious in his work, which is of a sedentary nature, but has no definite neurotic traits. The skin is dry, cracked, and flaking, and the affection is limited to the back of the fingers and the web area between the fingers. The condition varies much in severity; exacerbations are heralded by the appearance of small white nodules deep in the surface of the skin. Two independent dermatologists have suggested a functional element, with no definite diagnosis, and prescribed phenobarbitone, but this has been ineffective.*

A.—The use of the term "atrophic" is probably inaccurate. It does not tally with the "white nodules"—by which is presumably meant the deep vesicles of pompholyx—or cracking and flaking of the webs between the fingers. It is unlikely that two dermatologists would suggest a functional disturbance for an affection that was atrophic. With such loose terminology it is difficult to suggest a diagnosis, but the condition is probably a constitutional eczema. The question of adjustment to environmental conditions at home and work may need further attention. Fractional doses of x rays and bandaging the fingers independently at night, with Lassar's paste as a local application, are suggested. Soap and water and unnecessary cleaning of the hands should be avoided, liquid paraffin being used for cleansing purposes. It is important to be certain that there are no contacts outside work which may be causing trouble, as gardening, photography, or other hobbies and occupations.

Coronary Occlusion and Local Heat Therapy

Q.—*A patient aged 50 had a coronary occlusion eleven months ago; he has recovered and is now back at office work. He suffers from an old lumbago and I would like to try infra-red rays—is there any contraindication?*

A.—If the patient is capable of a full day's work at his office his former coronary occlusion is no contraindication to infra-red ray treatment for his lumbago. His heart should be able to stand the increased circulation of blood induced by local application of heat to a small area, with the resulting vasodilatation and lowered peripheral resistance.

Sensitivity to Sulphonamides

Q.—*Is it possible to desensitize an individual who is hypersensitive to sulphonamides? A man aged 74 took prontosil for a cold in 1934; six months later he had prontosil again, but after taking two tablets in 48 hours swelling of the lips, tongue and soreness of the mouth developed. Six months later he tried again and with similar results. A fortnight ago, an incision of the gum for extraction of an unerupted tooth, a tablet of penicillin was inserted. Some degree of the same symptoms ensued, and it was found that 1 gr. (65 mg.) of sulphapyridine was combined with the penicillin. Can anything be done to enable him to take sulphonamide compounds?*

A.—Stomatitis and glossitis sometimes accompany the "drug fever" type of reaction to sulphonamide drugs. The occurrence of these symptoms as the sole evidence of hypersensitivity is uncommon, though it has been reported. It seems probable that glossitis of this type is not due to hypersensitivity in the narrow sense of the word; it has been suggested that it is related to an alteration in the bacterial flora of the mouth or to a conditioned vitamin deficiency. Desensitization to sulphonamides has been carried out, but the process is arduous for the patient and would certainly be unjustifiable at the age of 74 years. Re-ort must be made to penicillin when infections need control.

NOTES AND COMMENTS

Spread of Tuberculosis by Books.—Dr. R. HARDY (Kingston-upon-Hull) writes: Dr. T. Peirson (May 7, p. 832) is obviously dissatisfied with the answer given in "Any Questions?" (April 2, p. 601) to a correspondent's question on this subject. I want to refer him to the *Lancet* (1943, 1, 81), where editorial comment was made and a short review of the then available literature was given, both with reference to the tubercle bacillus in books. To recapitulate briefly, C. R. Smith (*Amer. Rev. Tuberc.*, 1942, 46, 549) specially studied the transmission of infection from books, papers, etc., and found that the bacillus was viable from 2 up to 15 weeks in the dark at room temperature, but only for a few days in room light. Printer's ink did not affect survival rates of the bacillus, which lived as long on printed as on plain paper. In paper made from wood pulp the pH value of 5-6 was below the optimum for cultivation of the tubercle bacillus; in other words the medium was too acid for growth and propagation. "Book quarantine"—storage of books for four weeks on a dry book-shelf—was advocated as being effective in the disinfection of naturally contaminated books. Smith's conclusion was that the risks in lending-libraries were not very great. McCartney (*Lancet*, 1925, 2, 212) had already expressed a similar view, regarding books as insignificant transmitters of infection relatively to other fomites. Well-worn books, especially when read by children or handled by infants, are potentially infective not only in regard to tubercle but to a variety of other infections. They should be (and invariably are) weeded out continually from public and other lending-libraries. The problem is less important by far as a public health problem than the potential transmission of infections from crockery, cutlery, glasses, etc., used communally in cafés and public houses, and should be viewed in that light. Greater risk of infection by tubercle (and "droplet" infection at that) may be incurred during a 3-hour cinema or theatre show on almost any winter evening than by perusal of the most dilapidated book from the library shelves. And in the case of books "terminal" disinfection of hands can at least be done by the more fastidious of bibliophiles.

Vaccine Lymph.—Dr. DAVID SACKS (London, W.9) writes: I was surprised to read (May 7, p. 818) of the methods of expulsion of vaccine lymph from capillary tubes. The methods suggested, both by the Ministry of Health and Dr. O. H. Bowen, seem to be rather cumbersome. My method consists of snapping off both ends of the capillary tube with a pair of scissors which have been passed through a flame, applying one open end to the patient's linear scratch and the other end to my lips. A slight expiration and presto! the lymph is expelled. I cannot see the point of using sterilized teats, hypodermic syringes, etc., for this very simple procedure. Is sterility desirable for the patient's or the physician's safety? My father has been practising this method for 30 or more years, and neither he nor I have had anything but excellent results. A complete vaccination, including the linear scratch, the lymph expulsion, and the application of a piece of strapping over the area takes two minutes by this method.

Absorption of Mercury.—Dr. MARIE C. STOPES (Dorking) writes: Concerning your reply to the question about the absorption of mercury by women using contraceptives containing it ("Any Questions?" May 14, p. 879), may I say that very many years ago when I first started my work I found that women were dangerously ill, some even died, because of using compounds of mercury as contraceptives? I therefore profoundly deplore the recent recurrence of a much advertised commercial product containing mercury, for, although it may not injure all women, it certainly injures some. Your last sentence, saying that the risk would be increased "in cases in which the remains of the contraceptive were not removed by douching," also grieves me, for douching after coitus is a deplorable habit with bad psychological as well as physiological results, and we find it best, after over 25 years' experience, to advise against all douching. It is never necessary if the right bland suppository is used.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Atiology, Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Britmedads, Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra, Westcent, London*.

SUPPLEMENT TO THE BRITISH MEDICAL JOURNAL

LONDON SATURDAY JUNE 11 1949

THE SECRETARY REPORTS

THE TOWN AND COUNTRY PLANNING ACT

After July 1, 1948, all development of land (unless specially exempted) will attract a development charge which will be assessed by and payable to the Central Land Board.

Development, for this purpose, includes building operations such as enlarging a house or the erection of a new house, and material change in the use of land or of buildings such as the use of a house as an office. In general, anyone who effects a change in any of these senses will need planning permission before proceeding, though certain minor operations and changes of use do not require permission. Information on whether planning permission is needed and forms of application, when required, may be obtained from the local council offices.

If development which requires planning permission is carried out without such permission, the new structure may be required to be pulled down or the change of use of land or building may have to be discontinued.

The amount of development charge payable is determined by the Central Land Board. This board has established regional offices throughout the country, the addresses of which can be obtained from the local council offices. Broadly, the development charge will be the difference between the value of the land or building for its existing use and its value with permission to carry out the development.

The general effect of the Act is to take away development value from the landowner and to provide compensation for those who under the scheme mentioned below are entitled to such compensation and who before June 30, 1949, submit claims for the loss of that development value. When all claims have been received and examined the global compensation sum of £300 million set aside by the Government will be the subject of a scheme of distribution which Parliament will be asked to approve. Payments from the fund will be made not later than June 30, 1953, in the form of negotiable Government stock. The claims for payment must be sent to the Central Land Board before June 30, 1949, on a special form—Form S.1—which may be obtained from the offices of any county, borough, urban, or rural district council. In the L.C.C. area the application form may be obtained from the County Hall, Westminster Bridge, London, S.E.1, or in the City of London from the Town Clerk's Office, 55-61, Moorgate, London, E.C.2.

No payment from the compensation fund can be made unless the development value is (a) more than £20 per acre and (b) more than one-tenth of the restricted value. The restricted value for this purpose is the market value of the interest in the land restricted to its existing use. The term "existing use" includes, among other things:

(a) the rebuilding, enlargement, improvement, or alteration of any building existing on July 1, 1948, so long as its size is not increased by more than 10%, or in the case of a house 1,750 cubic feet* if that be greater;

(b) the rebuilding, enlargement, improvement, or alteration (with similar permissible increase) of a building destroyed or demolished since Jan. 7, 1937;

(c) the use as two or more separate dwelling houses of any building used on July 1, 1948, as a single dwelling house;

(d) the change of use within certain classes of purpose (e.g., a grocer's shop to butcher's shop, a cinema to a theatre).

Exemptions

Certain changes of use are not regarded as development for the purposes of the Act where the new use is for a purpose of the same class as the existing use. One of the classes within

*This is the size of an average garage.

which such a change is exempt is prescribed by the Minister of Town and Country Planning as follows:

Class XVI.—Use (other than residentially) as a health centre, a school treatment centre, a clinic, a crèche, a day nursery or a dispensary, or use as a consulting-room or surgery unattached to the residence of the consultant or practitioner.

Other classes of interest to the profession are:

Class XV.—Use (other than for persons of unsound mind, mental defectives, or epileptic persons) as a convalescent home, a nursing-home, a sanatorium, or a hospital.

Class XVII.—Use as a hospital, home, or institution for persons of unsound mind, mental defectives, or epileptic persons.

It appears from this, for example, that the conversion to a health centre of a consulting-room or surgery unattached to a practitioner's residence would not be regarded as a material change of use incurring a development charge.

The Minister has expressed the opinion that the use by a professional man, whether a doctor or dentist, of one or two rooms in his private dwelling for the purpose of consultation with patients would not constitute a material change in the residential character of the existing use so long as the professional use remains ancillary to the main residential use, though the use of the same house wholly for professional purposes would be another matter.

While the use of one or two rooms in a doctor's house for surgery purposes does not constitute a change of use sufficiently material to attract a development charge, the conversion of a house into a nursing-home or guest-house may incur liability to a development charge.

Application for Compensation

Some owners who have no intention of doing anything to their property may regard it as unnecessary to apply for compensation. The view has been expressed that in such cases it would be wise to submit a claim if there is a potential development value. For example, a house situated in a main street may be worth double its value if converted into a shop.

The better view, perhaps, is that a medical practitioner who considers that his land (which includes the buildings on it) has a potentially higher value for use for a different purpose than it has for its existing use would be well advised to submit a claim for compensation before June 30, 1949.
